These formulæ are based on the idea that impact must vary with the time of application of the load. On a long bridge even a high speed train only reaches its position of maximum bending moment after several seconds, so that the bridge deflects slowly to its maximum deflection and goes very little beyond what the train at rest would produce. This applies to main members. Floor beams and their attachment, however, receive maximum stress very rapidly, for the train advances to full effect in the brief space of one panel length. On floor stringer end-connections the first end is loaded absolutely instantaneously; the stringer itself takes its maximum load in about half a panel length, and so on: each member is to be allowed for impact according to the time required from its first feeling the load to the time of maximum moment. No simple load can produce an impactive stress more than double its static stress, but a swaying locomotive may have more than half its load on the wheels of one side, so that a wheel which may cause a maximum load on, say, the first end of a floor stringer, may happen to be loaded at the moment perhaps 30 per cent. more than its half share of the load on its axle, and at the same time it may happen that the balance weight is just delivering its downward hammer blow. Thus care is needed to give ample strength to details even of larger bridges, but the main members of a large bridge are but little affected by the trivial details of locomotive swaying, hammer blow, &c.

(*W. H. Booth.*)

Formula for the most suitable Span and Number of Piers for Iron Railway Bridges.

The object of the empirical formula is to determine for a bridge of given length, the number of spans required to make the cost of the work a minimum.

Let H = the total height of each pier measured from bottom of foundation; L = total length of bridge; $r = \frac{\text{price of cubic yard of masonry}}{\text{price per ton of iron}}$; n = number of piers.

For a double line: $n = 0{\cdot}063\ L\sqrt{\frac{L - 10\ r\ H}{r\ H\ L}} - 1$. For a single line: $n = 0{\cdot}04\sqrt{\frac{L - 10\ r\ H}{r\ H\ L}} - 1$.

These formulæ do not apply where H exceeds 98 feet.

Bridge-Expansion End Rollers.

Pressure per lineal inch of roller must not exceed 300 times the diameter of the roller in inches. (*Cooper.*)

The American Bridge Company's Specifications require rollers to be at least 4 ins. in diameter, and to have a maximum load per lineal inch of $1{,}200 \times \sqrt{\text{diameter}}$. By this rule the load per inch of diameter per lineal inch would be 600 lbs. for a 4-inch roller, and 400 lbs. for a 9-inch roller.

Swing Bridges.

P = 0·015, for rim-bearing; $P = 0{\cdot}15\ W\frac{r}{R}$, for centre-bearing;

$H.P = \frac{P\ v}{550}$; $v = \frac{R\ \pi}{2\ t}$;

P = Force required to turn the bridge, acting in centre line of track; W = total moving weight, in pounds; H.P = horse-power; r = radius of pivot; R = radius of centre line of track;

v = maximum linear velocity in centre line of track in feet per second ; t = time, in seconds, in which maximum velocity must be obtained, or one-half the number of seconds required to open the bridge.

The foregoing formulæ for frictional resistance generally give results in excess of the power actually needed under ordinary conditions, and practically cover all contingencies.

If the bridge has to be operated by hand-power, the gearing has to be arranged either for the number of men available or for the time required to turn and operate the bridge. In calculating the strength of the gearing, etc., the power of one man should be taken at 125 lbs., as this is about the force a strong man, with a foothold, can exert for a short time.

PERMISSIBLE UNIT STRESSES, IN POUNDS PER SQUARE INCH.

Kind of Strain, and Loading.		Structural Steel.	Axle Steel.	Steel Castings.	Cast Iron.	Rolled Copper.	Brass.

	(*B*)	6,600	8,000	5,000	2,000	—	—
	(*C*)	3,300	4,000	2,500	1,000	—	—

A. For a static load.

B. For a varying load producing stresses of tension or compression only.

C. For a varying load producing equal maximum strains in opposite directions, accompanied by shocks and vibrations.

The permissible unit stresses for bending (given opposite *B*)—10,000 for cast steel and 4,000 for cast iron—should be used for determining the strength of toothed gearing. The teeth in cut gearing should conform to the following proportions :—

P = pressure on tooth in pounds ; s = permissible unit stress ; p = pitch, in inches ; f = face of tooth, in inches ; y = a factor.

$$P = s\,p\,f\,y.$$

For wheels moving at slow speed (up to about 100 ft. per minute), where strength only is to be considered, $y = 0{\cdot}05$.

The strength of uncut teeth should be computed for a face of one and one-half times the pitch, or

$$P = \frac{3\,s\,p^2\,y}{2};$$

which conforms approximately with the assumption that the pressure is carried on one corner of the tooth.

For higher velocities, which tend to increase the shock and wear, this value should not exceed :—

$$y = 0{\cdot}05\ \frac{10}{\sqrt{v}} = \frac{0{\cdot}5}{\sqrt{v}}$$

where v = velocity in pitch circle, in feet per minute.

For bronze wheels, the same values should be used as for cast iron.

Fixed Bearings.

For the permissible unit pressures for fixed bearings of different metals, those in the table for compression, should be used.

Pressure, in Pounds per Linear Inch, on Rollers at Rest.

Cast iron, $400d$; Rolled and cast steel, $800d$; Where d = diameter of roller, in inches.

Moving Bearings.

PERMISSIBLE UNIT PRESSURES FOR BEARING ON ROTATING AND SLIDING SURFACES.

Maximum bearing values for rotating and sliding surfaces in pounds per square inch.

Bearings on which the Speed is slow and Intermittent.	
Pivots for swing bridges, hardened tool steel on special phosphor-bronze	3,500
Trunnion bearings for bascule bridges, axle steel on phosphor-bronze	2,000
Wedges, cast-iron on bronze	600
Wedges, cast-iron on cast-iron or structural steel	500
Screws which transmit motion on projected area of thread	200
Ordinary Cases, Parts moving at Moderate Speeds.	
Hardened steel on hardened steel	2,000
Hardened steel on bronze	1,500
Tool steel (not hardened) on bronze	900
Structural steel on bronze	600
Cast-iron on structural steel	400
Cast-iron on cast-iron	400
On crosshead slides, speed not exceeding 600 ft. per minute	50

In order to prevent heating and seizing at higher speeds, the pressure on pivots or foot-step bearings for vertical shafts and journals should not exceed :—

$$\text{On pivots, } p = \frac{160000}{n\,d}\text{ ; on journals, } p = \frac{300000}{n\,d}$$

where n = number of revolutions per minute ; d = diameter of journal or pivot, in inches.

For crank pins and similar joints with alternating motion, the limit bearing values given in the above formula may be doubled.

Roller and Ball Bearings.

(See Section XIX, page 899.)

Quantity of Land required for a Line of Railway.

This depends upon the width as determined by the depth of cuttings and height of embankments. Assuming average depth and height of 3 feet, and slopes of 1½ to 1, 5 to 6 acres will be required per mile of single line (4 ft. 8½ ins. gauge), made as in England, exclusive of sidings or stations. For each foot added to or deducted from the average of 3 feet given above (same slopes), 1 yard in width, or ⅛ acre per mile, must be added or deducted.

Light or Narrow-Gauge Railways.

Narrow-gauge railways will be found very suitable in districts where a standard-gauge line could not be made to pay, on account of the greater cost of construction and working of the latter. Narrow-gauge railways occupy less land, and the earthworks are of a less expensive kind than for standard-gauge lines, as heavy embankments and cuttings can be avoided by adopting sharper curves than are admissible with the standard gauge.

For the permanent way light material can be used, the rolling stock can be constructed to give a more favourable proportion between the dead and the paying loads than is possible on

standard-gauge lines, particularly if the traffic is made up of a great number of small consignments. On narrow-gauge lines the average proportion of dead load to paying load may be taken at about 1 to 2·33.

Whether steel or wood sleepers should be used is principally a question of cost, but it should be borne in mind that steel sleepers have a much greater life than wood sleepers.

The gauge and weight of rail should be determined in every case after a careful inquiry into the earning powers of the line. For the rails a weight of 25 lbs. per yard would be about the minimum. The 2-ft. gauge has the great advantage that it can be worked best in combination with portable railways which are joined on to branches of permanent line and continued to the farmyards, fields, or factories. The 2-ft. gauge is especially suitable for private lines and for lines of public utility with limited goods and little passenger traffic. It can be worked at a speed of fifteen miles per hour with curves 100 to 150 feet radius and gradients 1 in 80, for public lines; while on private lines, curves down to 60 feet radius and gradients up to 1 in 25 are admissible, according to the speed required and the amount of traffic. For lines with extensive goods traffic or principally for passenger traffic, 2 ft. 6 in. or 3 ft. gauge would be preferable.

The cost of transhipping goods from main line into narrow-gauge waggons and *vice versa* amounts on the Festiniog line to :—

Minerals	$\frac{3}{4}d.$ per ton
General Goods	$1\frac{1}{2}d.$ „
Slates which have to be transferred by manual labour	$6d.$ „

These figures also agree approximately with the Continental experience on this point.

If the goods are of a nature that they will not stand handling, the narrow-gauge waggon bodies could be made of such dimensions that three or four would fit into one main-line truck. A very simple device is also in practical use, of putting the main-line trucks on specially constructed bogies, and thus transporting them over the narrow-gauge railway.

(*A. Koppel.*)

The use of locomotives is not profitable on gauges of less than 18 inches.

The speed on narrow gauges may be as follows :—

2 ft. 0 in. gauge, 15 miles per hour.	3 ft. 0 in. gauge, 25 miles per hour.
2 ft. 6 in. gauge, 20 miles per hour.	3 ft. 6 in. gauge, 30 miles per hour.

Formulæ for Calculating the Power of Electric Locomotives for Light Railways.

W = weight of locomotive in tons loaded for service ; g = percentage grade (rise per 100) ; L = weight of load in tons.

$$W = \frac{12+g}{120-g} \times L.$$

T = tractive force in lbs.

$$T = 2{\cdot}24\,(g+12)\,(W+L).$$

H = effective horsepower at driving wheels ; S = speed in miles per hour.

$$H = \frac{T \times S}{375}.$$

C = current in ampères ; E = electromotive force in volts at the motor terminals ; m = mechanical efficiency of motor at 80 per cent. of H, allowing 20 per cent. for friction and electrical leakage.

$$C = \frac{H \times 746}{E \times m}.$$

For example : If

$g = 18$ (*i.e.* 18 ft. per 100 ft.) ; L = 15 tons ; S = 10 miles per hour ; E = 500 volts

then

$$W = \frac{12+18}{120-18} \times 15 = \frac{30}{102} \times 15 = 4{\cdot}4 \text{ tons.} \quad T = 2{\cdot}24 \times 30 \times 19{\cdot}4 = 1{,}304 \text{ lbs.}$$

$$H = \frac{1304 \times 10}{375} = 35 \text{ H.P.} \quad C = \frac{35 \times 746}{500 \times 0{\cdot}8} = \text{about 66 ampères.}$$

Hence the dynamo required would be of $66 \times 550^{*} = 36{,}000$ volt-ampères = 36 kilowatts.

Per kilowatt in the dynamo, there would be required, $1\frac{3}{4}$ H.P. in the steam engine,

or for 36 kilowatts, $36 \times 1\frac{3}{4} = 60$ H.P.

The strength of the dynamo must be calculated for the strongest current required.

For an installation intended to supply electricity both for lighting and power, a dynamo of 110 or 220 volts is the most suitable ; if, however, the lamps are in circuit, a dynamo of 500 volts

* This is the electromotive force at the dynamo terminals. Generators for tractive work are usually constructed for 550 volts, and allow of a loss of 50 volts between the dynamo and the motor terminals.

may be used. The advantage of the higher voltage is that the conductors may be made of a smaller section, while the loss of electromotive force remains the same.

The maximum loss of electromotive force can be taken at 20 to 25 per cent. of the voltage at the dynamo terminals.

By Ohm's Law,

$$E_1 = C \times R ,$$

where E_1 = loss of electromotive force along conductor in volts; C = current in amperes; R = resistance of conductors in ohms.

If

d = diameter of copper wire in inches; W = weight of rails in lbs. per yard; l = length of track in yards,

Then

$$R = l\left(\frac{1}{30000\,d^2} + \frac{1}{1100\,W}\right), \text{ and, } E_1 = C \times l\left(\frac{1}{30000\,d^2} + \frac{1}{1100\,W}\right).$$

(*A. Koppel.*)

Tunnels.

When deeply buried, a tunnel in soft earth is properly formed when its section is an ellipse whose major and minor axes have the ratio $c = \frac{\text{horizontal axis}}{\text{vertical axis}} = \sqrt{\frac{1 - \sin\phi}{1 + \sin\phi}}$, where ϕ is the angle of repose of the material. The horizontal axis must never be less than this ratio, but may be greater and will be still safe in firm earth. The whole ellipse is used in drains, but in tunnels the lower fourth or third is omitted, and a flat invert is put in.

Where tunnels are not deeply buried below the surface, the form of section is the 'Geostatic' arch, derived by transformation from the 'Hydrostatic' arch. To design a geostatic arch, given the depth of the crown below the surface $= x_o$, first design a hydrostatic arch and contract its horizontal ordinates in the ratio $c : 1$. This will give the figure required. As the greatest horizontal width will be a fixed quantity, the problem resolves itself into finding the depth below surface of the greatest hydrostatic breadth.

If x_o = depth of crown below surface; s = half span of geostatic arch; ϕ = angle of repose of earth; w = weight of a cubic foot of earth in lbs.; $c = \sqrt{\left(\frac{1 - \sin\phi}{1 + \sin\phi}\right)}$ = ratio of horizontal ordinates of two arches; y = half span of hydrostatic arch $= s \times \frac{1}{c}$; $s = cy$; $c = \frac{s}{y}$; x_1 = depth of greatest horizontal diameter $= x_o + a$; a = rise of arch above greatest diameter; b = a function depending on the relations of x_o, a, and x, then

$$b = a\sqrt[2]{\frac{x_o + a}{x_o}}\ (1);\quad y = b - \frac{b^2}{30a}\ (2);\quad b = y + \frac{y^2}{30a}\ (3);\quad x_o = a\frac{a^2}{b^2 - a^2}\ (4).$$

By assuming a value for a in (1) the value of b may be found and placed in (2); if a does not agree with its value assumed, further trials can be made until a sufficiently approximate result is obtained.

If r_o = radius of hydrostatic arch at crown; r_1 = radius of hydrostatic arch at greatest horizontal diameter or depth, x_1; k_o = geostatic crown radius $= r_o c^2$; k_1 = geostatic radius at depth $x_1 = \frac{r^1}{c}$; then

$$r_o = a + \frac{a^2}{2x_o};\quad r_1 = a - \frac{a^2}{2(x_o + a)};\quad r_o = \frac{a^2}{1}\left(1 + \frac{b^2}{a^2}\right);\quad r_1 = \frac{a}{2}\left(1 + \frac{a^2}{b^2}\right).$$

Thickness of Walls $= \sqrt{\cdot 12R}$ up to $\sqrt{\cdot 48R}$, where R = greatest radius $= \frac{a^2}{s}$.

Pressure on Brickwork $= \frac{w[x_1(s + t) - 0{\cdot}8\ a.s]}{t}$ lbs. per square foot, where w = weight per cubic foot of earth.

Breadth of Footings.—If t_1 = breadth of footings, then t_1 must not be less than

$$\frac{W}{2}\left\{\frac{(1 - \sin\phi)}{(1 + \sin\phi)}\right\}^2, \text{ where W = half width of bricked tunnel.}$$

To Draw the Hydrostatic Arch (figs. 579, 580).—Make $ab = r_o$ and $cd = r_1$; from d strike an arc with radius $de = fb - cd$; from a with radius af draw arc cutting this at e. Then d, e, and a are centres to strike half arch.

The radius of the hydrostatic arch at any point is inversely as its depth at that point below surface, hence $r_o x_o = r_1 x_1 = r_n x_n$. Through mud the section will be practically the hydrostatic

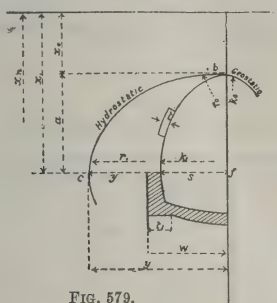

FIG. 579.

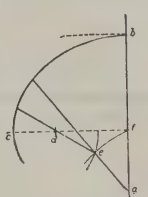

FIG. 580.

unless deeply buried, when the circular form would be correct; for in very soft material an invert resisting as an arch would be impracticable. An invert, however, could be used if strong enough to act as a beam against the upward pressure.

Superelevation of Outer Rail

When a vehicle runs round a curve it tends either to overturn or to run off the line.

The tendency to run off is counteracted by a high centre of gravity for the vehicle, because this throws a heavier pressure on the outer rail and keeps down the wheel flanges from mounting. Low centre of gravity produces detrusive effects upon the rail, and tends to force the flange over the rail. Every speed has its proper degree of superelevation which brings in gravity to balance centrifugal force. The superelevation necessary for sharp curves and high velocities would cause slow trains to run off the rail at the *inside* of the curve. In practice the maximum superelevation is limited to 7 or 8 ins., and the speed round the curve is regulated to fit that superelevation.

To determine the Superelevation of the Outer Rail of a Railway Curve.

Let v = speed of train in miles per hour; r = radius of curve in feet; G = gauge in feet.

$$\text{Superelevation in inches} = G \times \frac{v^2}{1{\cdot}25r} = \frac{v^2}{r} \times 3{\cdot}77 \text{ for 4 ft. } 8\tfrac{1}{2} \text{ ins. gauge.}$$

TABLE SHOWING SUPERELEVATION OF OUTER RAIL FOR A GAUGE OF 4 FT. 8½ INS.

2,000	·19	·75	1·70	3·01	5,000	·07	·30	·68	1·21

PRACTICAL RULE FOR DETERMINING THE SUPERELEVATION OF THE OUTER RAIL OF ANY CURVE. (*Price.*)

Let v = speed of train in feet per second; c = length of chord, in feet, whose versed sine equals the superelevation required; G = gauge of railway in feet; then

$$c = \tfrac{1}{2} v \sqrt{G}.$$

For 5 ft. 3 in. or 4 ft. 8½ in. gauge, and a speed of 40 miles per hour, c is approximately equal to 66 feet, or a Gunter's chain.

Stretch a 66-foot tape as a chord on the rail of the curve the superelevation of which it is required to find. Measure the distance of the rail from it at its centre point. This distance will equal the superelevation.

RADII OF CURVATURE AND VERSED SINES FOR RAILS.

The above radii are those corresponding (commencing at the top) to angles of deflection from 20 to 1 deg.

Upon sharp curves it is customary to widen the gauge ½ in. for curves of a radius of 750 to 1,000 feet, ¾ in. for a radius of 500 feet, and 1 in. for curves of a less radius.

Angles and Leads of Crossings.

Let R and r = radii of curves in feet; G = gauge of railway in feet; L = lead of crossing in feet (*i.e.* the distance from the nose of the crossing to the nose of the switch); θ = angle of crossing.

Curve Curving off a Straight.

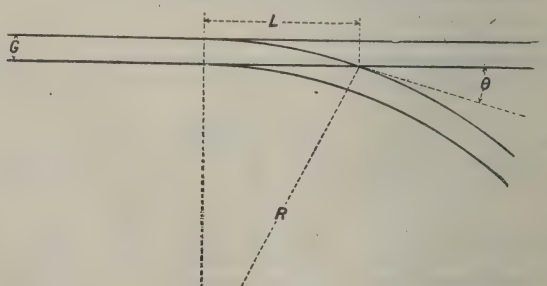

FIG. 581.

$$L = \sqrt{G(2R - G)} = \sqrt{2RG} \text{ (approximately)}; \qquad \sin\theta = \frac{L}{R}.$$

It is in some instances, where trains have to run fast over a crossing, thought necessary to adopt a curve with a larger radius than usual. In this case it may be considered advisable, in order to prevent an elbow occurring at the heel of the switch, to adopt a longer switch than usual. The length of the switch can be calculated from the following formula when the curve is off a straight.

$$\text{Length of switch} = \sqrt{2\mathrm{R}(c + t - e)},$$

where c = the clearance between the rails and the heel of the switch (in feet), this is usually about 2 inches; t = thickness of head of rail; e = the projection of the nose of the switch, if any.

Two Curves Curving in Opposite Directions.

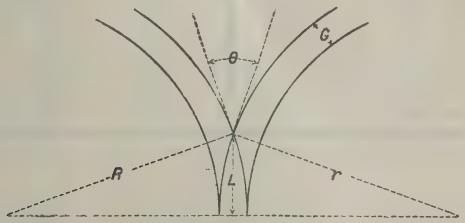

FIG. 582.

$$\mathrm{L} = \sqrt{\frac{2\mathrm{R}r\mathrm{G}}{\mathrm{R} + r}} \text{ (approximately)} \qquad \sin\theta = \frac{2\sqrt{2\mathrm{R}r(\mathrm{R} + r)\mathrm{G}}}{2\mathrm{R}r + (\mathrm{R} + r)\mathrm{G}}.$$

Two Curves Curving in the Same Direction.

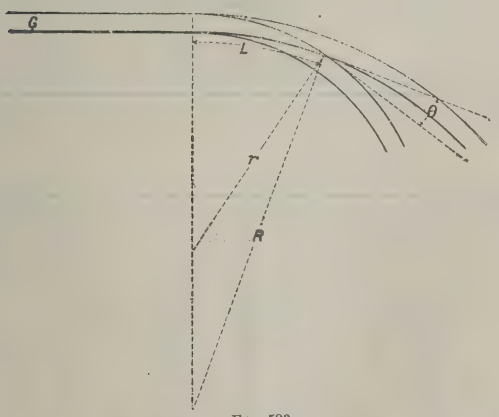

FIG. 583.

$$\mathrm{L} = \sqrt{\frac{2\mathrm{R}r\mathrm{G}}{\mathrm{R} - r}}; \qquad \sin\theta = \frac{2\sqrt{2\mathrm{R}r(\mathrm{R} - r)\mathrm{G}}}{2\mathrm{R}r + (\mathrm{R} - r)\mathrm{G}}.$$

Approximate Rule for Leads of Crossings.

The lead of any crossing is equal to twice the gauge multiplied by the angle of the crossing.

If curves are carefully plotted to an enlarged scale of, say, 10 or 20, or often even 33 feet to an inch, the leads and angles of the crossings can be scaled off with sufficient accuracy for all practical purposes.

The gauge should be generally about 1 inch tighter at the nose of the crossing and points than anywhere else on the lead, in order to prevent the wheels having any lateral play.

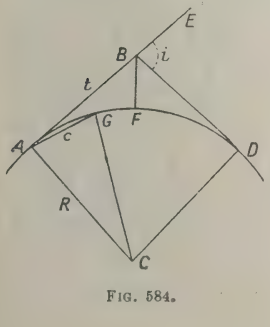

Fig. 584.

Ranging out Curves with a Theodolite.

R = radius of curve = AC. i = angle of inclination of intersection = EBD. t = tangent AB or BD = R tan $\frac{i}{2}$.

Length of curve = AFD = ·0002909Ri.

Tangential (or 'setting off') angle (angle between c and t) in minutes for any chord c

$$= 1718{\cdot}873\ \frac{c}{R}.$$

R and c being expressed in feet and i in minutes.

The angle ACG is called the 'deflection' angle, and is twice the tangential angle, *i.e.* the tangential angle is one-half the deflection angle.

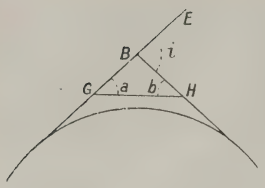

FIG. 585.

To find the Angle of Intersection and Point of Intersection where the latter is inaccessible.

If B is the inaccessible point, then—
Range the line GH.

$$i = a + b,$$

$$GB = \frac{GH \sin b}{\sin i}, \quad HB = \frac{GH \sin a}{\sin i}.$$

A curve in America is expressed as an $n°$ curve (deflection angle), and is one of such a radius that a chord of 100 ft. subtends an angle of $n°$ at the centre.

Setting out Curves by Offsets

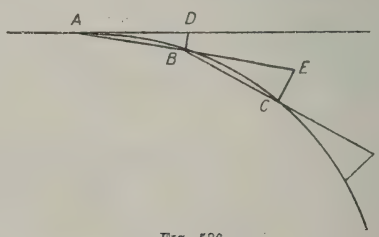

FIG. 586.

First offset BD from the tangent line.

$$DB = \frac{AD^2}{2 \text{ radius}}.$$

Offset from any chord AB produced

$$E = EC = \frac{AE \times EB}{2 \text{ radius}}.$$

Or where AB = BE, then

$$EC = \frac{AB^2}{\text{radius}}$$

(*C. E. Murray.*)

V=versed sine in inches. R=radius of curve in chains.

NOTE.—If 33-foot chords are used for finding curves, the versed sine measured must be multiplied by 4 and then looked up in this table.

Transition Curves.*

The superelevation of the outer rail on the curve which is needed at its full height for the whole length of the curve renders it necessary to begin canting the rails some distance back along the straight, called the 'run off,' in order that it may attain its full amount at the tangent point. To obviate the sudden centrifugal effect and also the difficulties due to the 'run off,' *transition curves*, or *spirals*, have been introduced. A true transition curve should determine, by slowly increasing its curvature, that the centrifugal force is applied gradually, and thus prevent any sudden oscillation, and also so that the full superelevation is gained gradually throughout its length.

The superelevation at any particular point in the transition curve should be the correct one for the curvature at that point, on the assumption that it has been designed to suit a certain maximum speed.

The formula $L = \sqrt{R}$, where L is the length and R the radius of the curve, gives very efficient transition curves for circular curves of less than 56·8 chains radius, which corresponds to about the maximum velocity used on any of our railways—84 miles per hour. But for curves of larger radius than 56·8 chains, the formula $L = 0{\cdot}00072428 \frac{V^3}{R}$ should be used, where V is the velocity in miles per hour, and L and R are in chains.

The formula $L = \sqrt{R}$ for determining the length of transition to be used has much to commend it, though it is used very little on British railways as yet, the custom at present being to take a length of 50, 60, or sometimes 66 ft. for every inch of superelevation on the circular curve. It might seem to a permanent-way engineer that the length provided by this formula for transitions to sharp curves was much too small, for instead of increasing in length as the curvature becomes sharper, it diminishes, consequently making the rate of gain of superelevation much quicker than 1 in. in 60 ft. But as the curves are sharper, the maximum speed permitted on them is also less, and thus in surmounting the superelevation at a lower velocity no uncomfortable motion is felt by passengers, as the discomfort of the motion varies as the cube of the velocity, a speed of 50 miles per hour causing nearly 5 times as much oscillation as that due to one of 30 miles per hour.

Again, for speeds of 70 and 80 miles per hour and a radius of between 40 and 60 chains, it may seem that the lengths of transitions are much too long, but here the excessive speeds demand a very gentle gradient on which to gain the full cant if the sensation of having the coach heaved up at one side is to be sufficiently gradual. Thus at speeds of 70 to 80 miles per hour the gain of superelevation should amount to 1 in. in 80 ft. or more if the best running is to be obtained. Therefore a general rule of, say, 1 in. in 60 ft. for the cant on all transition curves is unscientific and not productive of the best results. All the principal railways have now taken to the introduction of transition curves, where possible, at some parts of their systems.

The feeling that circular curves of large radius provide sufficiently good running to render them immune from the transition innovation is one which should be dissipated. As long as large easy curves are used for only *moderately high speeds* the need for a transition curve is not great. But the tendency on some of our principal railways to insert curves only of large radius and without transition curves on their main lines is a mistake, as the approach to any of these curves by trains at *high speed* is necessarily accompanied by irregularities of motion which would not occur had it been made on a transition curve.

Speaking broadly, it may be said that it is only on curves of large radius that there is any great need for a transition approach, as these curves are generally associated with high speeds, whereas the sharper curves are excluded from lines intended for fast traffic. Also, it must be remembered that on a high speed track an irregularity so slight as to escape the eye of the platelayer entirely may cause a very serious jar in the running at that point.

It is advisable that marks of a permanent nature be fixed along the 6-foot way, from which measurements may be taken to the curve in order to refix it in its true position and to the correct elevation during the operation of reballasting or other renewal work. The foreman platelayer should be provided with these and a plan giving the lengths of the offsets. A type of mark which has been adopted with some success is a centre peg made of a fish-plate set in a block of concrete, the fish-plate having a saw cut in it to indicate the centre line of the railway. It is not possible to fix these at the level of the rails, as their projection above the surface of the 6-foot way would be a danger to platelayers, also if a material train was unloaded at such a point a rail dropped on the marks would destroy their accuracy. However, if fixed well down in the pitching and formation so that the top surface of the plate is flush with the top surface of the sleeper or at a definite number of inches, say, 7 below the surface of the rail, they can be always used for re-establishing the rail in its correct position.

---

* Abstract from paper by Prof. S. W. Perrott, B.A., M.Inst.C.E., read before the Liverpool Engineering Society, March 7, 1917.

Another method, which has been used on the Great Southern and Western Railway in Ireland, is that of using short lengths of old flat-foot rails with the flange turned towards the line and placed so that the ordinary road gauge measured the distance from the outside of the running rail head to the flange of the rail used as a mark. These pegs were put in at intervals of 25 ft., either on the inside or outside of the curve (the line was single), as the ground was more suitable, and each was set so that its top was at the correct level of the corresponding rail at the point and the correct superelevation was marked on it with a punch.

The custom of making the length of the transition proportional to the number of inches of superelevation was adopted in America, probably for the purpose of obtaining easy hauling for freight trains travelling at a moderate speed. The Canadian Pacific Railway, as also some of the leading railways in this country, adopts 60 ft. for every inch of superelevation on the circular curve, but the former seldom uses more than 5 ins. of superelevation. Also, transition curves are only used for curves of superelevation of 3 ins. and upwards. The tendency in America is to keep down the superelevation as much as possible. This is for the benefit of freight trains, which are considered of primary importance but travel at lower speeds, as the higher superelevation means increased resistance to hauling, caused by the wheels binding against the lower rail. The American Railway Engineering Association has laid down the rule that, in all cases of 2 ins. of superelevation and upwards transition curves should be inserted.

The principal point of danger of a sharp curve is at its entry. If trains could be brought on to curves without any sudden irregularity of motion before settling down to the uniform motion on the curve, very much sharper curves could be adopted for high-speed trains than are used to-day. Indeed the results of experience and experiments seem to show that trains traverse curves of 5 chains radius at 35 miles per hour with perfect ease and without showing any tendency to leave the metals.

There is no hard and fast rule adopted in this country with regard to the number of points set out on the ground to fix each transition curve, the tendency being to fix 8 or even 10 points on a long transition curve and 6 on the shorter ones. A point at every half chain is generally sufficient, but some prefer to fix points about 1 chain apart at the tangent end and half that amount at the circular curve end. This gives good results, as the curvature is so much sharper at that end, and wants its position defining at nearer points.

On the Canadian Pacific Railway it is usual to set out the centre point and two-quarter points only in addition to the extremities, except in the case of very long transition curves. If these are set out by deflection angles from the beginning of the spiral they are in the ratio of 1 : 4 : 9 : 16 as they vary as the square of the length. Also if set out from the end of the spiral the ratio of the four angles is 11 : 20 : 27 : 32. So when any one of these angles is found (generally that to the end point) the others are easily calculated.

Setting out Spiral Points.

A convenient formula for setting out spiral points by deflection angles is the following :-

The deflection angle in minutes to any chord point is given by $\frac{N^2L}{10}$ where N is the number of chords between the point where the instrument is set and the required point, and L is the length of the chord in feet. This formula will not apply if the instrument is set up at the intermediate chord points.

The operation of calculating the deflection angle θ for any point in a transition curve can be easily and rapidly done in the field without the need of any offset tables, as $\theta_n = \frac{L}{6R}$, which can be determined immediately the length of the transition is decided upon. Consequently the operation of setting out the transition spiral by deflection angles from the spiral tangent point is as simple as setting out the ordinary circular curve by deflection angles.

Example of a Transition.

A transition spiral is required to connect a straight with a 25-chain curve.

Taking the length of the transition $= \sqrt{R}$, then L = 5 chains,

$$\therefore \theta n \text{ for the end of spiral} = \frac{L}{6R} = \frac{5}{150} = \frac{1}{30} \text{ radians},$$

$$\therefore \theta n = \frac{57^\circ 3}{30} = 1^\circ\ 54'\ 36''$$

If the points on the spiral are put in every half-chain, there will be ten deflection angles as follows :—

			°	′	″		°	′	″
θ_1	=	$(\frac{1}{10})^2$	(1	54	36)	=	—	1	8·76
θ_2	=	$(\frac{2}{10})^2$	(1	54	36)	=	—	4	35·00
θ_3	=	$(\frac{3}{10})^2$	(1	54	36)	=	—	10	18·84
θ_4	=	$(\frac{4}{10})^2$	(1	54	36)	=	—	18	20·16
θ_5	=	$(\frac{5}{10})^2$	(1	54	36)	=	—	28	39·00
θ_6	=	$(\frac{6}{10})^2$	(1	54	36)	=	—	41	15·36
θ_7	=	$(\frac{7}{10})^2$	(1	54	36)	=	—	56	9·24
θ_8	=	$(\frac{8}{10})^2$	(1	54	36)	=	1	13	20·64
θ_9	=	$(\frac{9}{10})^2$	(1	54	36)	=	1	32	49·56
θ_{10}	=	$(1)^2$	(1	54	36)	=	1	54	36·00

In setting out the same transition curve by deflection angles from its end, it is usual to calculate the deflection angles for the circular curve for the corresponding points, and deduct from each its deflection angle as given in the previous table.

The circular deflection angles are simply found as follows :—

$$\frac{1718'\cdot87}{R} = \frac{1718'\cdot87}{25} = 68'\cdot75,$$

which is the deflection angle in minutes for a whole chain ;

$\therefore$ 34′ 22″·5 is the angle for a half-chain.

The following table gives the deflection angles to be used with theodolite at point 10, in fixing points 9, 8, 7, etc.

(1) Deflection angle to point.	(2) Circular deflection angle.			(3) Corresponding values of θ_1, etc.			Difference between (2) and (3) giving deflection angles to spiral.		
	°	′	″	°	′	″	°	′	″

LOCOMOTIVES.*

SOME RECENT ADDITIONS TO BRITISH LOCOMOTIVES.

The L. & N.W.R. and G.W.R. continue to add to the number of four-cylinder engines of the 4–6–0 type. The G.C.R. is also building this type, the distinguishing feature being that all four cylinders are in line at the smoke-box. The inside pair drive the first coupled axle, and the outside pair, by means of extended piston rods, drive on the second axle. The piston valves of the outside cylinders have outside admission of steam, and the valves of the inside cylinders have inside admission. This enables the inside and outside valve on either side of the engine to be driven by separate arms on a common rocking shaft operated by Stephenson link motion inside the frames.

The 2–6–0 type mixed traffic engine, with wheels about 5 ft. 6 ins., is being built by the G.W.R., G.N.R., S.E. & C.R., and L.B. & S.C.R.

On the North-Eastern Railway three-cylinder engines of the 0–8–0 and 4–6–0 types have made their appearance, the former for mineral traffic, and the latter, with 5 ft. 8 ins. wheels, for mixed traffic. All three cylinders with their respective piston valves have the same inclination and are contained in one casting. A separate link motion is provided for each valve.

The G.N.R. is building three-cylinder engines of the 2–6–0 type, with 5 ft. 8 ins. wheels. The boiler barrel is 6 ft. in diameter, and made from a single plate $\frac{5}{8}$ in. thick by 11 ft. $5\frac{1}{2}$ ins. long. The firebox is 9 ft. long. The outside cylinders are inclined at an angle of 1 in 30, and the inside cylinder 1 in 8 : all three cylinders drive the same axle. Walschaert valve gear outside the frames is used for the piston valves of the outside cylinders. The piston valve of the inside cylinder is driven by a combination of rocking levers operated by the two outside valve gears.

The Caledonian Railway is building 3-cylinder engines of the 4–6–0 type, having a similar arrangement of valve gears.

On the L.B. & C. Railway several more large 4–6–4 type tank engines have been constructed.

For the purpose of assisting trains on the Lickey incline, Bromsgrove, the Midland Railway has introduced a 4-cylinder banking engine of the 0–10–0 type. The cylinders are inclined 1 in 7 and drive the third pair of wheels, the second axle being cranked to give clearance to the inside connecting rods. The cylinders are cast in pairs, and there is only one 10-in. piston valve to supply both cylinders on one side of the engine, the inside cylinder having crossed ports. Walschaert valve gear is used.

Locomotive Types.

The classification of locomotives is by wheel arrangement. Abbreviations are used, the Anglo-American system denoting in their order leading carrying wheels, coupled wheels, and trailing carrying wheels by number of wheels to each group. Where there are no carrying wheels at either end a cipher is added. The letter T denotes a tank engine. Articulated engines are denoted by the wheel arrangement of their separate parts. The Continental system merely states number of axles coupled and total axles of engine, and gives the proportion of adhesive weight without specifying the actual arrangement of wheels. In addition to identity by wheel grouping, the various types receive code names in America. Example:

Diagram.	Code Name.	Anglo-American Notation.	Continental Notation.
	Atlantic	4–4–2	2–5
	Mogul	2–6–0	3–4

In France it is usual to classify a locomotive by groups of axles in their order, instead of by wheels: thus a 4–4–2 engine is known there as type 2–2–1; and a 2–6–0 engine is expressed as type 1–3–0.

Another system, coming into use in Germany and Switzerland, is similar to the French, but groups of coupled axles are represented by letters—A for one driving axle, B for two, C for three, etc.: so that a 4–4–2 engine becomes type 2–B–1. A 2–6–0 engine is denoted by 1–C only, a cipher not being necessary to indicate absence of carrying wheels with this system.

Types of Locomotives most generally used on British Railways.

Tender Engines.

and *vice-versa*. Generally speaking, the total adhesion type (i.e. engines without carrying wheels) are mostly used for shunting and local work. Carrying wheels are added as the water and coal capacity are enlarged to permit of greater radius of action. The tank engines with two or more pairs of carrying wheels are capable of travelling considerable distances without replenishing fuel and water.

General Design of Locomotives.

The principal limitations governing locomotive design are:—

(1) *Loading gauge*, giving extreme dimensions as to heights and widths.
(2) *Rail gauge*, affecting stability, etc.
(3) *The track*, which limits the maximum axle load.
(4) *Bridges*, the strength of which restricts the weight per ft. run over total wheel base.
(5) *Curves*, which limit the length of engine and determine rigid wheel base.

Other factors to be taken into consideration are:—

(1) *Loads*, as to weight and type of rolling stock.
(2) *Gradients*, both ruling and maximum.
(3) *Resistance of curves.*
(4) *Speed.*
(5) *Prevailing atmospheric conditions.*

These are inter-related, load becoming a maximum for both directions of travel when there are no gradients or curves and the speed is low. An increase in speed or the presence of gradients, curves, and side winds reduces loads.

Some further points to be looked into when designing new engines are:—

(1) *Length and strength of turn-tables* and clearances round them.
(2) *Engine sheds*, as to clearances, length of pits, etc.
(3) *Coal stages*, height of platform, method of coaling, etc.
(4) *Position of water columns* at stations and in yards in relation to signals and points.
(5) *Distance between available coal and water supplies.*
(6) *Capacity of workshops*, in regard to load on cranes, length of pits and traversers, necessity for special tools, etc.

The bulk of the work on British railways is done by tender engines of the 0–6–0 type for good and 4–4–0 type for passenger trains. Many of these engines are of fairly recent construction. Some of the older engines have been brought up to date by being rebuilt with larger boilers fitted with superheaters and with new cylinders provided with piston valves. The goods engines usually have cylinders 19 ins. × 26 ins. and wheels 5 ft. 0 ins. diameter; the passenger engines 20 ins. × 26 ins. cylinders and 6 ft. 6 ins. wheels. Boiler pressure is about 180 lbs. per sq. in., but with high degree of superheat it is usually some 10 lbs. less, while the diameter of cylinders is increased a little to compensate. The single-wheel engines once so numerous are now almost extinct on British railways, as are also compound engines, except on the Midland Railway.

For heavy passenger work the 4–4–2 and 4–6–0 types are resorted to. The former has no more adhesion than the 4–4–0 type, but increased boiler power permits heavy trains to be hauled

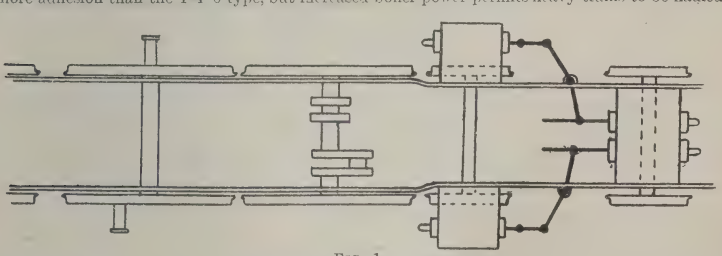

FIG. 1.

at high speeds. The 4–6–0 type can also take heavy trains at high speed or, alternatively, exceptionally heavy trains at moderate speed on account of its greater adhesive weight. For mineral traffic and long goods trains an eight-wheel coupled engine is used. The present tendency is to prefer the 2–8–0 to the 0–8–0 type, many of the latter having been converted to the former. The 2–6–0 type with wheels about 5 ft. 6 ins. is being used to an increased extent as a mixed traffic engine. It is especially suitable for fast goods, excursion trains, etc. In the large passenger and goods engines outside cylinders predominate. The advantages gained for the outside position are shorter wheel base, long connecting rods, no crank axle, direct drive through rods on all wheels horizontal cylinders. The distance between centres of cylinders is about 6 ft. 8 ins. and cannot

be reduced very appreciably on account of the necessity for finding sufficient bearing surface for coupling and connecting rods. Thus, the diameter of cylinders is limited by the remaining space within the load gauge, which varies on the different railways. Since the load gauge is at its narrowest near rail level, advantage can sometimes be gained by inclining outside cylinders so that they are brought up into a wider part of the gauge. The tendency to reduce wear and tear of boilers, by taking advantage of high superheat to economically lower steam pressure, results in

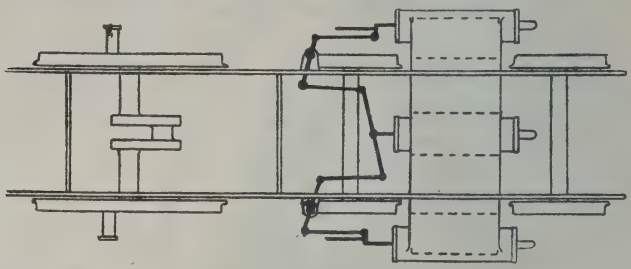

FIG. 2.

a demand for larger cylinder capacity. This can be met by increased diameter or stroke of cylinders, or both. Another way is to multiply the number of cylinders, hence three and four-cylinder high-pressure engines. Multi-cylinders are also being adopted for mechanical reasons, as they give better balancing and turning movement, less disturbance in running, subdivision of driving forces, increased bearing areas and other advantages. Multi-cylinder engines are necessarily more costly and complicated than two-cylinder. It is therefore desirable to reduce their working parts to a minimum. This can be done by providing two sets of valve gear only and operating the additional valve or valves through rocking levers attached to the valve gears. The arrangement adopted on the Great Western Railway four-cylinder engines is shown in fig. 1. Two sets of Walschaert gear drive the inside valves directly and the outside valves by means of rocking levers. The levers are not straight, the outer arms being set backwards, resulting in an

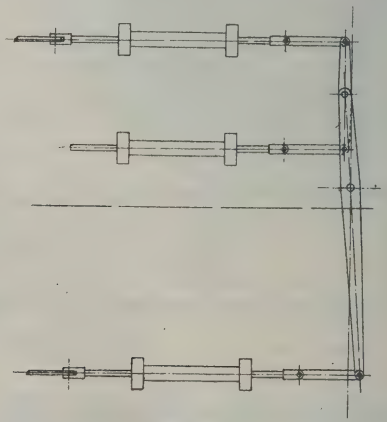

FIG. 3.

improvement of the valve events. The Lancashire and Yorkshire engines are similar to the above, but Joy's valve gear is used, and the rocking levers are straight with equal lengths of arms. The London and North Western engines have Walschaert valve gear outside the frames and work the inside valves through straight rocking levers. All cylinders drive on one axle.

Three-cylinder engines can be arranged in a similar manner, and the analogy is best shown by fig. 2, which illustrates Holcroft's three-cylinder system. The combined movement from two

outside valve gears is used for the additional valve, the shorter arms of rocking levers on either side of the engine being attached to each valve gear and the longer arms to a combination lever. The third valve is driven from the centre of this lever. When the cranks are at 120° to one another the arms of the rocking levers are in ratio 1 : 2. A modification of this design is in use on the Caledonian Railway, and some German engines are so fitted.

Fig. 3 shows Gresley's arrangement as used on the Great Northern Railway three-cylinder engines of the 2–6–0 and 2–8–0 types. A long lever at the front of the engine is pivoted to a cross stretcher on the frame, the ratio of the arms being as 2 : 1. The longer end is attached to the tail spindle of the right-hand valve. To the shorter end another lever with equal arms is pivoted at its centre. The outer end of this is attached to the spindle of the left-hand valve, and the inner end to the spindle of the inside valve, all valves being in line and set at the same inclination ; but in order that the crosshead may clear the leading coupled axle, the inside cylinder is inclined 1 in 8. The valves of the outside cylinders are, of course, directly operated by two sets of Walschaert valve gear. A variation of the same principle is in use in Germany, in which one rocking shaft having equal arms is mounted on the shorter arm of another rocking shaft having arms in ratio 2 : 1.

Four-cylinder high-pressure locomotives are in use on the Continent. In some of these there is a single piston valve for each pair of cylinders, one of which has crossed ports. In others a double-headed piston valve is used, as in the Dendy-Marshall system. British practice favours separate valves for each cylinder.

Four cylinders are more used in fast passenger engines. Since the forces and masses in each pair of motions are opposed, the balancing is good and the disturbances to smooth running reduced. The mechanical efficiency is high, but otherwise there is little advantage over two cylinders. Owing to the more regular turning moment, three cylinders are applied to engines in which the most is to be made of the available adhesion. The ' Atlantic ' type represents one instance and heavy shunting tanks another. In the latter instance there is the further advantage of six exhaust beats per revolution in place of four, with less disturbance to the fire when working slowly.

Tank engines are used for fast passenger trains on the Midland Railway (Tilbury section), Metropolitan Railway (Aylesbury extension), and to some extent on the London, Brighton and South Coast Railway.

Some recent American locomotives are of enormous size. For the heaviest freight traffic Mallet articulated compounds are in use on the Virginian R.R. weighing with tender nearly 400 tons, a pair of cylinders being added to the tender to make use of its adhesive weight, the total tractive effort being about 80 tons. On the Southern R.R. engines of the ' Mikado ' or 2–8–2 type are provided with steam tenders made from obsolete engines of the 2–8–0 type, in which the boiler is removed and a water tank substituted. For passenger traffic in mountain sections the Canadian Pacific Railway has engines of the 4–8–2 type with 5 ft. 3 in. wheels, cylinders 23½ ins. diameter by 32 ins. stroke, heating surface 5,123 sq. ft. and grate area 60 sq. ft. The axle loads on the Pennsylvania R.R. reach 30 tons. In order to reduce dynamic loading of wheels the reciprocating parts are of alloy steel. With small wheels the revolving masses must likewise be reduced, since it is not always possible to make the balance weights in the wheel large enough. Outside valve gears such as the Walschaert, Baker-Pilliod, or Southern are general, and piston valves are of large diameter with inside admission. The two-cylinder engine with superheater has superseded all compounds, except the Mallet type. Multi-cylinder engines are not favoured. Tank engines are uncommon, even switching engines having tenders.

TRAIN RESISTANCE.

Resistance of Air to Train.

(1) The area of resistance presented by the first carriage is its front superfices ; that of the following carriages, about 10 square feet, but depending upon the distance between them.

Q = resistance of air, in lbs. A = surface of resistance, in sq. ft. = about 70 ft. + $10(n-1)$ for railway waggons, where n = number of waggons in train. (54 ft. according to M. Vuillemin, &c., 50 ft. Unwin.) v = velocity, in feet per second. $e = 1{\cdot}43$ for a thin surface = $1{\cdot}17$ for a cube, = $1{\cdot}07$ for a train of 5 waggons, = $1{\cdot}04$ for a train of 25 waggons.

$$Q = {\cdot}0011896 e A v^2 \text{ (Pambour).}$$

(2) If P = pressure on the front ends in pounds per square foot ; V = velocity in miles per hour :—

$$P = {\cdot}00265\ V^2.$$

Assuming that the superficial area of the front end to be about 75 sq. ft., the following table shows the total pressure and the power required to overcome that pressure at various speeds :—

Speed in miles per hour.	Total pressure, lbs.	H.p.
20	79·5	4·24
40	318·0	33·92
60	715·5	115·28
80	1272·0	271·36
100	1987·5	530·0

It will be seen that at speeds below 40 miles an hour the effect of head end resistance is practically negligible; but at speeds of 60 miles an hour or more the power required to overcome head end resistance is by far the most important element in train resistance. As the number of cars in a train is increased, the relative effect of head end resistance is decreased.

An engineer of the firm which furnishes electric locomotives for the Simplon Tunnel says that at a speed of 50 miles an hour in the tunnel the air-resistance absorbs 400 horse-power, or 40 per cent. of the capacity of the locomotive, against 95 horse-power in the open air.

Resistance to Traction on a Level Railroad.

The most complete record of experiments on Train Resistance is probably that of Mr. J. A. F. Aspinall, given in a paper by him read before the Institution of Civil Engineers, November 26, 1901, and published in vol. 147, May 1902, of the Proceedings of the Institution. The conditions vary so much with the character of the train and other factors that no definite formulæ covering all cases and separating the various resistances making up the total can be given. The following are the principal formulæ given in the Proceedings referred to, abstracted from a list of 55, dating from that of Clark in 1855.

FORMULÆ FOR TRAIN RESISTANCE.

R = tractive resistance in lbs. per ton (2,240 lbs.).

V = velocity in miles per hour.

W = weight of engine and tender in tons (2,240 lbs.).

w = ,, carriages ,, ,,

A = area of front of train in square feet.

L = length of train in feet.

Resistance of Curves.

Resistance due to curvature of track varies inversely as the radius, and directly as the rail-gauge and length of rigid wheel base. It also depends to some extent on the state of the surfaces of wheels and rails. The practice of watering the rails or lubricating the flanges of the wheels lessens the resistance, whilst the occasional necessity of sanding the rails for the locomotive

greatly increases it. On main lines the curve resistance is usually very small, and no allowance is made for it. In special cases, where the curves are sharper, such as in sidings, station yards, or at junctions, it is sometimes necessary to form some estimate of the resistance. The American Master Mechanics' Association gives the resistance per ton (of 2,240 lbs.) as 0·77 lbs. for each degree of curvature of track in the case of cars (with bogies), and double this amount—1·54 lbs. —for locomotives.

In British practice, curvature is expressed by the radius in feet or chains. As 1° of curvature corresponds to a radius of 5,730 feet, the radius of any curve in degrees is given in feet by $\frac{5730}{x^\circ}$ or in chains by $\frac{87}{x^\circ}$.

$$\text{Resistance in lbs. per ton} = \frac{4412}{\text{radius in ft.}}; \text{ or } \frac{67}{\text{radius in chains}} \text{ for cars.}$$

$$\text{,, ,,} = \frac{8824}{\text{radius in ft.}}; \text{ or } \frac{134}{\text{radius in chains}} \text{ for locomotives.}$$

To find the equivalent up-gradient, 1 in n, that offers same resistance as curve :—

$$n = \text{radius in ft.} \times 0{\cdot}5.$$
$$= \text{radius in chains} \times 33.$$
$$= \frac{2871}{\text{curvature in degrees}}$$

Resistance due to Gradients on Railways.

The force, F, required to move 1 ton up a slope of 1 in n, neglecting friction and resistance of air $= \frac{1 \text{ ton}}{n} = \frac{2240 \text{ lbs.}}{n}$, or resistance in lbs. due to gravity on any incline $= \frac{2{,}240}{\text{rate of gradient}}$ per ton of train.

On a gradient of 1 in 300 the total resistance becomes about twice that on a level at a speed of 30 m.p.h., and therefore only half the utmost load can be carried, or the speed must be diminished. Gradients above 1 in 330 are considered first class ; 1 in 330 to 1 in 150, fair working gradients.

In American and Continental practice, gradient is given as rise per cent. or per thousand, so that grade of 1 in $n = \frac{100}{n}$ per cent., or $\frac{1000}{n}$ per thousand. Thus 1 in 300 = 0·33 per cent. or 3·3 per mille.

Rise in feet per mile $= \frac{5280}{n}$, or 17·6 ft. for 1 in 300.

Effect of Gradients on Speed of Passenger Trains.

The work done by the locomotive in a given time is proportional to total resistance × speed. For speeds over 25 m.p.h. on the level, the resistance of an average engine and train may be fairly represented in lbs. per ton by the simple formula $R = 5 + {\cdot}003v^2$. The work done on the level is therefore proportional to $v\,(5 + {\cdot}003v^2)$. On a gradient of 1 in n this becomes $v\left\{(5 + {\cdot}003\,v^2) + \frac{2240}{n}\right\}$. If the engine is capable of maintaining a speed of 60 m.p.h. on the level, and the horse-power output is constant, the effect of the gradients on the speed is as follows :—

Inclination	Level	1 in 2,500	1 in 1,000	1 in 750	1 in 500	1 in 250	1 in 150	1 in 120	1 in 100	1 in 90	1 in 80	1 in 70

Resistance of Locomotives

The resistance of a locomotive is a very uncertain quantity, and there is no formula which can take account of all the variables. There are, however, several formulæ which give results approximating to the average resistances in ordinary working.

The resistance may be divided into three components:—

(1) Internal resistance of engine machinery, including driving wheels.
(2) Resistance of locomotive as a vehicle, including head-on air resistance.
(3) Resistance of tender as a vehicle.

According to Prof. W. F. Goss, the internal resistance is fairly constant for any given cut-off for a wide range of speed, but that the later the cut-off, and consequently more even the turning moment, the less the friction.

As a vehicle the locomotive not only has the usual rolling resistance, journal friction, etc., but it has to encounter the atmospheric pressure on the surfaces perpendicular to the direction of travel, and it shelters to some extent the train behind.

The reaction of the steam pressure on the cylinder covers, applied alternatively to either side of the engine, causes it to move in a sinuous path and sets up further flange friction.

The tender has a resistance very similar to any other vehicle of the train, but it is modified a little by the movement of the engine to which it is closely coupled.

Prof. Goss gives as total resistance of engine and tender,

$$\mathrm{WR} = 3{\cdot}8\ \frac{d^2 l}{\mathrm{D}} - w(2 + \tfrac{1}{5}\mathrm{V}) - 0{\cdot}11\mathrm{V}^2,$$

where d = diameter of piston in inches, l = stroke in inches, D = diameter of drivers in inches V = speed in m.p.h., and w = total weight of engine and tender (W) less weight on drivers in tons (of 2,000 lbs.)

This formula does not take into account the increase in friction with the number of pairs of coupled wheels.

Mr. Lawford H. Fry gives separate formulæ for engines with 4, 6, and 8 coupled wheels, which in lbs. per ton (2,240 lbs.) of engine and tender can be expressed as :—

$$\begin{aligned} R &= 8{\cdot}5 + 0{\cdot}09V + 0{\cdot}004V^2 \text{ for 4 wheels coupled.} \\ &= 10{\cdot}0 + 0{\cdot}12V + 0{\cdot}004V^2 \text{ for 6 wheels coupled.} \\ &= 13{\cdot}4 + 0{\cdot}48V + 0{\cdot}004V^2 \text{ for 8 wheels coupled.} \end{aligned}$$

The equations are derived from the mean of the results obtained by numerous European experimenters. (*The Engineer.*)

About 22 lbs. per ton at 50 m.p.h. is the usual resistance of a British 4-4-0 type engine ; and at 60 m.p.h. some 4 h.p. per ton is expended in moving the engine and tender.

In order to see how much power the locomotive absorbed as compared with the train, a certain number of experiments were tried on the Lancashire and Yorkshire Railway, and it was found that the ten-wheeled engine No. 1392 absorbed 34 per cent, of the total horse-power. Mr. W. M. Smith (the Institution of Mechanical Engineers) gave the result of his experiments as about 36 per cent. of the total horse-power. Probably 34 per cent. or 36 per cent. was about the right percentage, other figures being much too high ; but the actual figure depends on the load behind the engine.

Train Acceleration.

The resistances to be overcome in moving a train are frictional and gravitational. Any draw-bar pull in excess of them is available for accelerating the train ; or

$$F = T - W(R_1 + R_2 \pm R_3),$$

where F is accelerating force in lbs., T is tractive effort in lbs., W weight of train in tons, and R_1 R_2 and R_3 the opposition to traction in lbs. per ton due to train resistance, curves and gradients respectively. A negative result indicates retardation.

For the actual acceleration or retardation produced, allowing 10 per cent. for rotary acceleration of wheels and axles,

$$a = \frac{F \times 32}{1{\cdot}10W \times 2240} = \frac{F}{77W} \text{ ft./sec.}^2$$

In American practice about 5 per cent. is allowed for rotary acceleration, as the car wheels are smaller in diameter and also bear a lesser ratio to the weight of car.

To produce a speed of V miles per hour in distance S feet,

$$F = \frac{82V^2W}{S} \text{ lbs. ; or } F = \frac{82(V^2 - v^2)W}{S} \text{ lbs., } v \text{ being initial speed.}$$

To produce a speed of V miles per hour in t seconds,

$$F = \frac{112VW}{t} \text{ lbs. ; or } F = \frac{112(V - v)W}{t} \text{ lbs.}$$

Power, Tractive Force, and Adhesion of Locomotives.

The pressure exerted on the piston is to the force exerted in the traction of the train inversely as the velocities of the piston and train, i.e., as twice the stroke of the piston to the circumference of the wheel.

Piston Speed.—Ordinary piston speed is about 900 feet per minute.

d = diameter of piston, in inches. a = area of piston, in sq. inches. l = length of stroke, in inches. p = indicated pressure per square inch, in lbs. D = diameter of driving-wheel, in inches. V = velocity, in miles per hour. n = number of revolutions per minute = $336\frac{V}{D}$.

$$\text{Tractive force at rails} = \frac{d^2 lp}{D} \text{ lbs.}$$

$$\text{Indicated horse-power} = \frac{d^2plV}{375D} = \frac{4anpl}{33{,}000} \times \tfrac{1}{12}.$$

The calculated tractive (or starting) effort

$$T = \frac{cd^2Pl}{D} \text{ lbs.}$$

where P = boiler pressure and c is a coefficient varying from 0·8 to 0·9. The lower figure more nearly represents the net draw-bar pull and the higher figure the effort at rim of driving wheels. There is no general rule. The Great Western Railway takes 90 per cent. of boiler pressure, the Great Northern and Great Central 85 per cent., the London and South Western and the South Eastern and Chatham 80 per cent. In American practice 85 per cent is usual.

The above relates to the ordinary two-cylinder high-pressure engines. Multiply results by 1·5 for three-cylinder, and by 2 for four-cylinder locomotives. (For compound locomotives see p. 589).

The horse-power given out at the draw-bar is less than the indicated horse-power by the amount expended in moving the engine and tender. This is approximately 400 h.p. in modern

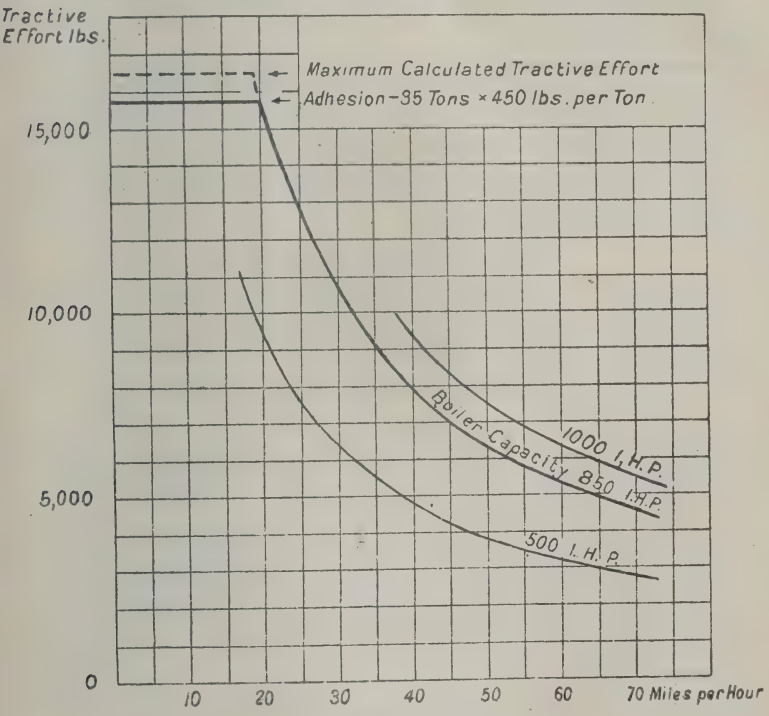

FIG. 4.

locomotives running at 60 m.p.h., representing about 35 per cent. of the maximum indicated horse-power. (See Resistance of Locomotives.)

Draw-bar horse-power = 5·97 × pull (in tons) × speed (m.p.h.)
or 0·0267 × pull (in lbs.) × speed (m.p.h.).

Ordinary locomotives are capable of developing from 9 to 12 horse-power for each ton of their weight (inclusive of tender).

T = tractive force at drivers ; t = draw-bar pull ; H = square feet of heating surface ; V = speed in m.p.h. ; d = diameter of piston in inches ; L = stroke in inches ; D = diameter of drivers in inches ; W = weight of engine and tender, less weight on drivers (in tons of 2,000 lbs.).

$$T = 161\frac{H}{V}. \quad ; \quad t = 161\frac{H}{V} - 3{\cdot}8\frac{d^2 L}{D} - W(2 + \tfrac{1}{6}V) - 0{\cdot}11\,V^2.$$

Professor Goss (*'Railroad Gazette,' Jan.* 17, 1902).

In the English climate it is not safe to count upon more than 450 lbs. of adhesion per ton of load on the coupled axles. (*E. A. Johnston*, 1913.)

The proportion of the weight on the driving wheels giving *adhesion* and available as tractive force varies considerably, from about 200 lbs. per ton in frosty and greasy weather to 600 lbs. in dry weather. It must, of course, exceed the tractive power, and is generally taken at about 350 lbs. per ton, this being quite feasible, as all locomotives are fitted with a sanding arrangement.

In average British practice, the factor of adhesion, that is, the ratio between adhesive weight and calculated tractive effort, is between 4 and 5 for four and eight-wheel coupled engines, and between 5 and 6 for six wheels coupled. In tank engines the factor varies with the amount of water and coal present.

The relation between horse-power, tractive effort, and adhesion, is shown by the characteristic curve of a locomotive in fig. 4, where tractive effort is plotted against speed. Horse-power appears on the diagram as a hyperbolic curve, since for any given horse-power pull × speed = a constant. In the example given the maximum calculated tractive effort is 16,500 lbs. The actual pull is limited by adhesion to 15,750 lbs., adhesive weight being 35 tons and the adhesion 450 lbs. per ton. The boiler capacity is taken as 850 i.h.p. and is plotted as a hyperbolic curve. The intersection of the curve with the maximum available tractive effort gives the lowest speed at which the boiler is fully used. Until this point is reached horse-power is limited by cylinder capacity or adhesion, as the case may be. Beyond it, the horse-power is approximately constant and the pull falls off as the speed rises. A deduction must be made for engine and tender resistance to obtain actual draw-bar pull.

Weight Restriction in Locomotives.

On English railways the heaviest load is 20 tons, but there are practically no lines in this country on which the permissible axle load exceeds 20 tons.

The axle loads carried with the goods engines are about 15 tons in Germany and Italy, 17 tons in England, Belgium, and France, and 23 to 27 tons in the United States.

The following is a formula given by F. J. E. Spring for locomotive driving-wheels :—

Safe load = 200 × diameter of wheel in inches × width of rail head on which wheel bears in inches.

In addition to restriction of individual loads on wheels, the total weight of a locomotive is limited by the strength of permanent-way structures. In designing a new locomotive, or rebuilding an existing one, it is essential to study the resulting bending moment imposed on bridges. This varies with the total length of engine, wheel base and spacing of wheels, and the weights on individual pairs of wheels. A short engine with the wheels close together may stress a bridge more than a heavier engine in which the weight is spaced over a longer base. The locomotive engineer, however, is not concerned in the actual stresses produced, but his problem is to keep within the boundaries of a limiting bending moment curve. The permanent way engineer sets out the strength of the weakest bridges of various spans, and from them deduces a curve showing the maximum equivalent uniformly distributed load that the different spans can sustain. The curve is either set out giving the total load on the spans, or the tons per foot run of span. In fig. 5 the upper curve shows a limit determined by the permanent-way engineer in lbs. per ft. run. No locomotive may run that sets up on any bridge a greater bending moment than this. If the excess is small, a slight modification of the wheel spacing or distribution of loads may rectify matters. As the locomotive constitutes a rolling load, any direct calculation is very tedious. The loads must be advanced across the span a foot or so at a time, and the bending moment ascertained for each step. It is obvious that maximum bending will occur under one of the loads, but it is not always certain which load it is. The maximum also changes from under one wheel to another at a certain point. The most satisfactory way is to first of all solve the problem graphically : if care is taken the results are very reliable. Once a solution is obtained the bending moment can be exactly calculated, and this acts as a check on the drawing and reading of scales. For the loading of the span it is assumed that there are several locomotives of the type under consideration, coupled together. As an example of the method, a 4–4–0 type engine is taken, the loads and spacing of wheels being shown on the line diagram at the foot of fig. 5. The first step is to set up a vertical line and mark it off to a convenient scale, say 1 in. = 10 ft., to represent the wheel loads to scale. Thus, *c*–*d* is the weight on the leading bogie wheels, *d*–*e* on the next pair, *e*–*f* that on the first pair of coupled wheels, and *f*–*g* for the trailing wheels. The loads on tender wheels are represented by *g*–*h*, *h*–*j*,

FIG. 5.

j–k. The length *a–b*, *b–c*, are tender wheels of the preceding engine; while *k–l*, *l–m*, are for bogie wheels of the following engine. If the span is a long one more loads must be added in their proper order. Having done this a pole O is taken, approximately in line with the centre of gravity of the loads, and at a distance of, say, 5 ins. from the vertical line. The various points on the line are then joined to the pole. The next step is to draw a horizontal base line and mark on it the wheel base of the engine to a scale of, say, $\frac{1}{2}$ in. = 1 ft. Verticals are projected through the points, and the spaces are lettered A, B, C, etc., to correspond with the letters *a*, *b*, *c*, etc., on the vertical load line.

Commencing at any convenient place, a line is drawn through space A parallel to the polar line *o–a*. This is followed by line through space B parallel to *o–b*, and so on until complete. For convenience a number of vertical lines are spaced at intervals representing each foot of the span. In order to ascertain the bending moment for a 10-ft. span, the intersection of a vertical with the curve is joined to another ten spaces away and scaling 10 ft. when measured horizontally. The next and succeeding points are treated in the same way, and it will soon be evident where the greatest bending moment is enclosed. This is equivalent to moving the bridge span along under the engine. Having ascertained the greatest bending for a 10-ft. span, that for a 20-ft.

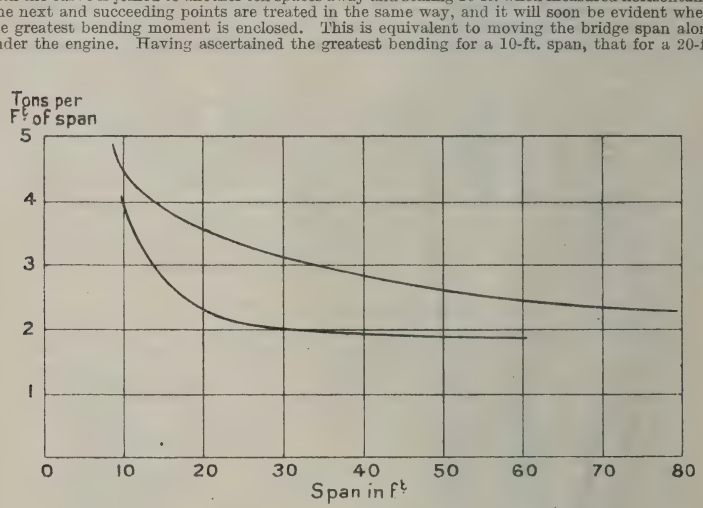

FIG. 6.

is obtained in the same way by joining verticals 20 ft. apart. The 30, 40, 50 ft., etc., spans are treated in like manner. It will be observed that the maximum B.M. moves from under the driving to the trailing wheels between 40- and 50-ft. spans. The maximum B.M. can be scaled by measuring vertically, and the results tabulated. If 1 in. = 10 tons of weight, and 1 in. = 2 ft. of span, and the polar distance is 5 ins., the scale of bending will be 1 in. = $10 \times 2 \times 5 = 100$ ton-ft. The final step is to obtain the equivalent uniformly distributed load by equating each result to it—i.e., B.M. $= \frac{WL}{8}$, so that $W = \frac{8 \times \text{B.M.}}{L}$, where W = total distributed load on span. For load per ft. run of span, B.M. $= \frac{w l^2}{8}$, and $w = \frac{8 \times \text{B.M.}}{l^2}$.

The results obtained can be plotted on the bridge curve supplied by the permanent-way engineer (as the lower curve in fig. 6), and unless all the plotted points fall below the upper curve, the design of the engine will have to be modified in some way, either by reduction of weight, or possibly by an alteration to the wheel base, or the addition of another pair of wheels.

When the position of maximum bending and the loads producing it are known, calculation is a simple matter, and it acts as a check on the graphical working. The position of load system giving maximum bending is such that the centre of span bisects the distance between point of maximum bending and centre of gravity of loads on span.

Detailed Weights of Parts of a Locomotive.

LIST OF THE ACTUAL WEIGHTS OF THE VARIOUS PARTS OF A GREAT EASTERN RAILWAY GOODS ENGINE AND TENDER, V 14 CLASS.

ENGINE.

Boiler.

	t.	c.	q.	lbs.
Boiler shell, dome, and dome cover (steel)	3	11	2	14
Tube plate (steel)	0	4	3	6
Boiler mountings	0	7	1	0
Foundation ring (wrought iron)	0	3	2	11
Fire-hole ring (wrought iron)	0	1	1	9
11 longitudinal stays (wrought iron)	0	7	0	19
Support for longitudinal stays	0	0	2	13½
Regulator rod (wrought iron)	0	1	0	0
Internal steam pipes (copper)	0	1	1	20
4 angle irons for roof bar slings (steel)	0	1	1	8
2 angle irons for expansion brackets	0	0	3	16
Angle iron for regulator	0	0	0	2½
2 hand rails	0	0	1	15
	5	1	1	22

Fire-box.

Copper fire-box	1	5	2	5
8 roof bars (cast steel)	0	13	0	10
Roof bar bolts (wrought iron)	0	1	0	9
8 roof bar slings	0	0	1	24
16 roof bar sling pins	0	0	1	16
633 copper stays, 1 in. diameter	0	6	0	7
	2	6	2	15

Tubes.

250 tubes, 1⅝ in. outside diameter (steel)	1	14	0	4
	1	14	0	4

Smoke-box.

Smoke-box door (wrought iron)	0	4	0	11
„ front (steel)	0	2	0	10
„ side plates (wrought iron)	0	3	0	27
Smoke-box door lugs and pin	0	0	0	10
Hand rail complete	0	0	0	23½
Dart	0	0	0	19
Cross bar and pins for dart (wrought iron)	0	0	2	17½
2 castings for cross bar	0	0	0	20½
Blower	0	0	0	10
„ pipes (external)	0	0	0	11
„ rod	0	0	0	24½
Chimney (barrel wrought iron, base steel)	0	1	1	19

Compounding Locomotives.

Design of Compound Locomotives.—Considerations regarding the design of compounds are :—Cylinder proportions ; ratio of the area of the high to the low pressure, the latter being generally regarded as at least twice that of the former ; intercepting or starting valves ; steam port area of the low-pressure cylinder ; receiver capacity ; and absence of restricted passages, obstruction and abrupt turns between the high and low-pressure cylinders.

The general claim by most authorities is a saving of about 20 per cent. in steam. Expansive working, and consequently exhausting at a low temperature, is the main object ; but, providing the difficulties of compression are overcome, it has a formidable competitor in the simple locomotive.* Cylinders have been employed larger in proportion to the boiler for expansive working in simple engines, but failed from evident reasons known to locomotive experts.

* *The Engineer*, December 21, 1917.

Ratios of the Areas of the High-pressure Cylinders to the Low-pressure.—Worsdell, Von Borries, and others, 1 to 2–2½; Webb, 1 to 2·3; Vauclain and America, 1 to 3. In modern compounds ratio is 1 to 2·4 on Midland Railway, 1 to 2·5 Mallet compounds in U.S.A., and about 1 to 2·2 on Continent.

Tractive Force of Compound Locomotives.—Von Borries, who recommends a ratio of 1 : 2·2 or 2·3, gives tractive power of two-cylinder compounds as,

$$\text{T. F.} = \frac{psd^2}{4\,\text{D}},$$

where p = boiler pressure, s = stroke in inches, D = diameter of wheel in inches, and d = diameter of low-pressure piston.

For four-cylinder compounds, Baldwin gives

$$\text{T.F.} = \frac{2\,psc^2}{3\text{D}} + \frac{psd^2}{4\text{D}}.$$

c being diameter of high-pressure piston.

Another formula is given as

$$\text{T.F.} = \frac{0{\cdot}8\,psd^2}{(r+1)\text{D}} \text{ for two-cylinder compounds,}$$

and

$$\text{T.F.} = \frac{1{\cdot}6\,psd^2}{(r+1)\text{D}} \text{ for four-cylinder compounds,}$$

r being ratio of low to high-pressure piston area.

Modern High-power Locomotive Economy in France.*

The results of recent locomotive operation on the Paris, Lyons and Mediterranean Railway (M. Maréchal, Chief Mechanical Engineer) are claimed to show a very great progress over the most economical results hitherto obtained from what were considered to be the best modern high-power superheated steam locomotives; these results exceed some of the highest obtained from modern Corliss-geared superheated steam compound stationary engines, and are quite equal to several recent test results with the largest turbine central station electrical sets in the world. These new P.L.M. locomotives develop over 2,500 horse-power at the quite moderate speed of 43 miles per hour, and almost maintain that power at the highest speeds, as, for example, 2,427 horse-power at 75 miles per hour. They haul trains of 645 tons net, or of 800 tons gross, up a continuous incline rising 1,060 ft. in 82½ miles, at an average rate of 52 miles per hour, equivalent to a train load of 1,000 tons hauled at 50 miles per hour on straight and level line.

The feed water consumption averages, on the distance of 100 miles between Paris and Dijon, 13¼ lbs. per indicated horse-power with a train of 646 coach tons, and the same also for a light load of only 383 coach tons. The steam consumption per indicated horse-power of these P.L.M. engines is 6·13 kilos, as compared with 4·55 kilos for the 20,000-kilowatt turbo-alternators (electric power condensing engines) at Chicago. The following is a summary of results:—

Per Horse-power per Hour at the Draw-bar.	Tons.
Coal economy per 1,000 tons of coal by compounding	= 351
Compound coal consumption, as against 1,000 tons in single expansion	= 649

Coal Consumption per 35,000 *Horse-power Hours at the Draw-bar.*	Tons.
Simple expansion	98·8
Compound	58·9
Coal saving in each 90 tons coal	= 31·9

	Simple.	Compound.
Number of engines in service to which these results refer	91	44
	Tons.	Tons.
Weights of 'Pacific' engines in average working trim	92·8	91·2

Mean Horse-powers Indicated with Fourteen Trains from Laroche to Blaisy-Bas (82·5 *miles*).

Simple.		Compound.	
Minimum.	Maximum.	Minimum.	Maximum.
1,734	1,896	2,025	2,182

It will be seen that, for every 35,000 horse-power hours as registered at the draw-bar, the compound engines consume 58·9 tons of coal, as compared with 90·8 tons of coal by the modern superheated steam single-expansion engines of the same 'Pacific' type. The coal saving is therefore 31·9 tons in every 90·8 tons consumed by the simple engines. With a coal consumption of 298 tons, the simple engines hauled 76 trains of the average weight of 383 tons, while the compounds hauled 100 trains of the average weight of 558 tons, and also in the same total time per train.

As the result of twelve tests of each system, made with equal train loads, the simple system

* *The Engineer*, June 8, 1917.

aggregated 412,390,000 kilogram-metres at the draw-bar in an average time per train of 81 min. 40 sec., while the compound system aggregated 446,460,000 kilogram-metres at the draw-bar in an average time per train of 78 min. 54 sec., and in simultaneously saving 6 tons of coal, or average of 1 ton of coal in each 82·5 miles run with the regulators open.

As the result of fourteen tests, inclusive of two tests of heavy trains of about 645 coach tons, the average load hauled by the compounds amounted to 558 coach tons, and their average train time was practically the same as that averaged by the simple expansion system in hauling an average load of only 383 coach tons.

The general average coal saving per draw-bar horse-power per hour by compounding was 35 per cent.: 30 per cent. the coal saved per indicated horse-power, 33 per cent. the saving of water per draw-bar horse-power, and 31 per cent. the saving of water per indicated horse-power.

The indicator diagrams showed that, per unit of steam pressure and per cubic foot of steam admitted to the cylinders, at any given speed, the average compound piston pressure was between 35 and 40 per cent. greater than that which was indicated in single-stage working; while in consequence and for any given boiler pressure the trains behind the compounds ran proportionately faster unless their loads were made suitably heavier. In general service the train load was greater, per official ratings, by 10 per cent., with higher speed and less coal.

In one of the sets of tests the two-stage principle resulted in a coal saving of 43 per cent. The water saving per indicated horse-power hour was only $9{\cdot}36 - 6{\cdot}48 \div 9{\cdot}36 = 30$ per cent., while on the effective horse-power hour at the draw-bar the water saving was only $14{\cdot}77 - 9{\cdot}29 \div 14{\cdot}77 = 37$ per cent., which differences between the steam and the water economies during the same trip incidentally prove that compound expansion certainly does not owe its economy to avoided condensations—as is almost universally claimed—since the water saving is very much less than the steam saving, while the coal saving—43 per cent.—corresponds more nearly to the steam saving than to the water saving—37 per cent.—when all the three economies are based on the horse-power hours at the draw-bar.

The P.L.M. indicator cards showed that the steam saving by compound expansion is quite as great at 75 miles per hour as it is at 25 miles per hour, and that the old disrepute of the compound, that it was uneconomical at high speeds, has been overcome.

Cylinders of Simple and Compound Locomotives of Equivalent Power.

The following table has been compiled and put into practice for proportioning the diameters of the cylinders of 2-cylinder and 4-cylinder compound locomotives when designing them to generate a power equivalent to that of a given size of simple cylinder and of the same piston stroke. Hitherto the average ratio of area of the simple cylinders and the high-pressure cylinders of compound locomotives was 1 to 1·17 and 1·026 for 2-cylinder and 4-cylinder engines respectively. This has been found to be too low in practice, with the result that new ratios of 1·25 for the 2-cylinder and 1·10 for the 4-cylinder have been proposed and are in use. The table gives the area of the simple cylinders from 12 ins. to 22 ins. diam., with the corresponding diameters and areas of the high-pressure cylinders of the compound locomotives. In the case of the 4-cylinder engines the area given is that of the sum of the two high-pressure cylinders.

TABLE SHOWING ACTUAL AND RELATIVE AREAS OF SIMPLE AND OF 2-CYLINDER AND 4-CYLINDER COMPOUND LOCOMOTIVES.

Simple.			2-cylinder Compound Ratio, 1·25.		4-Cylinder Compound Ratio, 1·10.

(Railroad Gazette.)

THE NORTH EASTERN RAILWAY'S STUMPF LOCOMOTIVE. SUPERHEATED.

The fundamental feature of the Stumpf engine is the extraction of the energy from the steam without causing the steam to return on its path. The flow is constantly in one direction from the hot inlet ports to the relatively cold outlet ports. In the ordinary steam engine the flow it reversed at the end of each expansion stroke and each exhaust stroke. During the exhaust stroke of such engines the clearance space surfaces are cooled down by the cold wet steam, and as a result the next incoming volume of hot live steam suffers considerable initial condensation. In the Stumpf engine this cooling of the clearance surfaces is avoided, with the result that initial condensation is almost entirely absent. The Stumpf cylinder is double-acting, with an inlet port at each end and a common exhaust port at the centre. The exhaust port is constituted by a series of holes drilled round the walls and leading into an exhaust belt formed integrally with the cylinder casting. The piston employed is of exceptional length and fills approximately half of the cylinder volume. In fact, at the end of each stroke one or other of its edges is just clearing the ring of holes and allowing exhaust to take place. Thus each half of the cylinder volume has to deal with the steam from only one inlet port. As the total area of the exhaust port is large the period of exhaust extends from a short time before the end of the stroke is reached until a short time after. The bulk of the one stroke is thus occupied with the admission and expansion, and the bulk of the other with the compression of the steam. In general, the period of exhaust covers one-tenth of the stroke each way, so that admission and expansion occupy nine-tenths of the stroke in one direction and compression nine-tenths of the stroke in the other.

The cylinders are 20 ins. diameter and 26 ins. stroke, and are about twice as long as cylinders of the same stroke, but of the ordinary pattern. The pistons are hollow castings with spring rings at each end. The admission of steam to the cylinders is controlled by piston valves placed on top and actuated by Walschaert's valve gear. The valves have inside admission, their maximum travel being $6\frac{1}{2}$ ins. and their exhaust lap $1\frac{3}{4}$ ins. When the engine is running in full gear the valve ports provide an auxiliary exhaust, but when the engine is notched up this auxiliary exhaust is closed and all the steam escapes by way of the central ring of ports. The engine is fitted with a superheater capable of maintaining a steam temperature of 600° to 640° F. (*Sir Vincent L. Raven.*)

Parts of Locomotives.

CYLINDERS.

Diameter of cylinder in inches = $\cdot 75\ \sqrt{\text{I.H.P.}}$, where I.H.P. = maximum H.P. that engine will be required to develop continuously for any length of time. Stroke and diameter of driving wheels should be so proportioned that the piston speed is about 900 ft. per minute, as this is found to be the most economical speed. Thickness of barrel in inches = $\cdot 02\ d + \cdot 75$, where d = diameter in inches. Thickness of metal of steam passages may be $\cdot 7\ t$ and of the flanges $1 \cdot 25\ t$, where t = thickness of barrel in inches. The studs for the cylinder cover should be calculated for a stress of 4,000 lbs. per square inch, to allow a large margin of safety in case of priming.

Area of steam port $d^2 \div 15$ in the best modern practice. Length of ports should not be less than $\cdot 85\ d$. Area of exhaust port should be two and a half times that of the steam port.

Clearance between cylinder covers and piston is usually made from $\frac{1}{4}$ in. to $\frac{3}{8}$ in. The *clearance volume*, including the passages, varies from 6 to 8 per cent. of the cylinder volume. If the clearance is too small the compression line at high speeds rises above the steam chest pressure, and the engine does not run well.

Cylinders for Highly-superheated Steam.—Owing to the very high temperatures, it is necessary that the steam chest walls should be separate from the walls of the cylinders. There is a very great variation in the temperatures of superheated steam, on the one side, and of the exhaust steam on the other. If a common wall is used between the two the result is that the cylinders are liable to fracture. (*H. N. Gresley*, '*Proceedings, Inst. Loco. Engineers.*')

VALVES.

For Flat Slide Valves.—Outside lap usually = $0 \cdot 8a$, where a is the width of the steam port As a rule there is no inside lap, but in some cases a small inside clearance not exceeding $\frac{1}{16}$ in. is allowed. The *lead* is about $\frac{1}{8}$ in., and the *maximum travel* is about $2 \cdot 7a$. Valves of tank engines and others that make frequent stops should be of soft grey cast iron. For long-run engines, 5 parts copper, 1 part tin. (*Wolff.*)

VALVE OPENING.

Taking the mean effective area of opening in square inches per 500 sq. ft. of heating surface based on existing average practice of twelve railroads, the following empirical formula has been developed :

$$A = \frac{0 \cdot 10266 \times HS}{P}.$$

Where A equals the effective area of opening of the valve in square inches, H S equals the heating surface of boiler in square feet, and P equals the absolute pressure, equals gauge pressure plus 15 lbs. The formula is based on an evaporation of 5·28 lbs. of water per square foot of heating surface per hour. (*American Railway Master Mechanics' Association.*)

Cylindrical Valves.

Cylindrical or piston valves are extensively used in connection with superheated steam. A large proportion have internal admission of steam. Various packings are in use; some consist of segmental collapsible rings pressed against the liners by steam pressure; others have spring rings, of which there are several kinds. The advantages over flat slide valves are reduced friction, larger port opening, and wear is confined to the easily renewable packing rings.

The diameter of piston valves is about half that of the cylinders.

Piston valves are of two kinds, inside admission and outside admission. In the former steam is admitted between the heads, and exhaust takes place on the outside. The advantages are reduced area for radiation of heat and packing of spindle is only subjected to exhaust steam pressure. Outside admission valves are arranged like flat slide valves, with admission of steam on outside and exhaust inside.

VALVE GEAR.

With inside cylinders Stephenson valve gear (see Section XXIX, Part VI) is general. In special cases, where eccentrics must be dispensed with, Joy's valve gear is used. Outside cylinder engines, with the valves inside the frames, also have the Stephenson gear; but when the valves are outside the Walschaert valve gear is now preferred.

The outside cylinder engines on the Great Western Railway have 10-in. piston valves placed above the cylinders worked by Stephenson gear from the inside of the frames. The maximum valve travel is 6¼ ins., the lap being 1⅝ ins., and the port opening 1½ ins., although the steam ports are 1⅞ ins. wide. The eccentrics are set to give ¼ in. lead at 25 per cent. cut off, resulting in the valves being about ⅛ in. blind in full gear. This arrangement gives a sharp cut off, prolonged expansion and a free exhaust, resulting in large mean effective pressure at high speeds.

Walschaert Valve Gear.

The Walschaert valve gear, figs. 7 and 8, is mainly used on outside cylinder engines. The travel of the valve is derived from two movements, the crosshead of the engine and a return

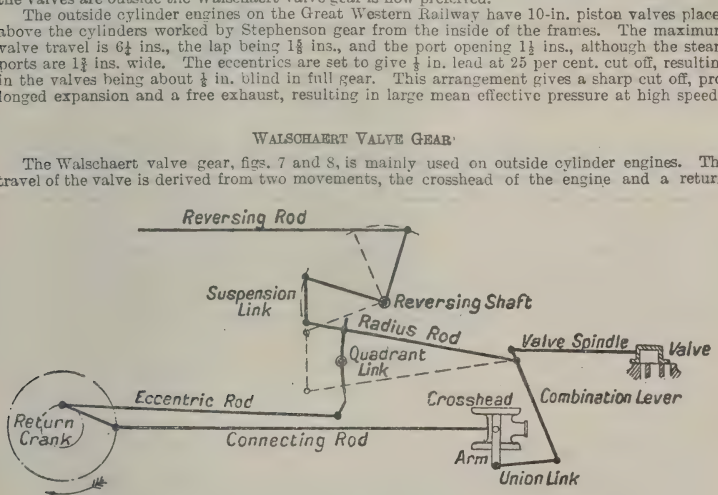

Fig. 7.

crank attached to the main crank pin, or, in the case of inside cylinder engines, from an eccentric on the crank shaft. The first movement is a reproduction of the travel of the crosshead to a reduced scale, the reduction being effected by a combination lever connected at its lower end to the crosshead through a link. In order that the angular movement of the lever shall not be too great by any restriction of length an arm is rigidly attached to the crosshead so that the lever may be suitably lengthened. The combination lever is also attached to the valve spindle and to the radius rod which forms its fulcrum. With an outside admission valve the valve spindle is attached above the radius rod and with inside admission of steam the positions are reversed (see figs. 7 and 8). The function of the combination lever is to give the mid-gear travel, equal to twice 'lap + lead,' and the lever is so proportioned that the stroke is reduced to this amount. The lead is constant for any length of travel.

The second movement, derived from the return crank, is transmitted to a quadrant link rocking on fixed bearings. The maximum angle through which this link swings should be kept within 45°. The radius rod is attached to the link through a die block and communicates its motion to the valve by way of the combination lever. This second movement is at a phase of 90° with the first, and its magnitude can be varied and its direction reversed by altering the position of the radius rod on the quadrant link. In mid-gear the second movement is nil, only the first

movement being communicated to the valve. The position of the radius rod in the link is regulated by the reversing shaft, the attachment being either a vibrating suspension link (see fig. 7) or a slider consisting of a die block working in a long slot, as in fig. 8. In the latter case it is more convenient to use the bottom of the link for fore-gear running, while in the former either top or bottom can be used, since it is only necessary to alter the position of the return crank, which is nominally 90° ahead or behind the main crank. For convenience of design the quadrant

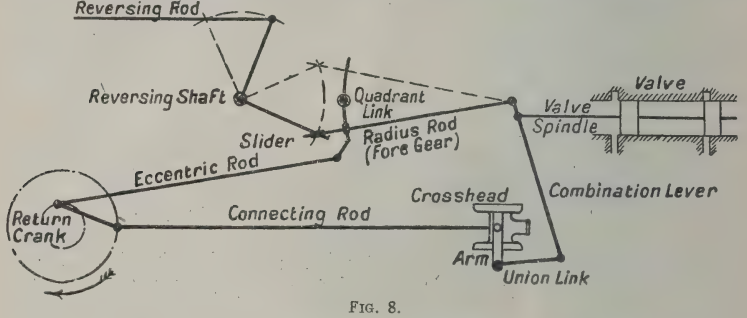

FIG. 8.

link is usually raised so that the eccentric rod is inclined, and this angle of inclination should be taken into account when setting the return crank, being added to or subtracted from the main angle of 90°. The setting of the return crank is as follows :—

Valve.	Fore Gear.	Return Crank.
Outside admission	At top of link	90° behind main crank
" "	At bottom of link	90° in advance of main crank
Inside "	At top "	90° in advance of "
" "	At bottom "	90° behind "

CRANK AXLES.

If W = weight of engine in tons, when in working order ; D = diameter of driving wheels in inches ; then

$$d = K\sqrt[3]{WD}.$$

For the best modern practice, K = ·522. (*Wolff.*)

Dimensions taken from the crank axles of a number of modern British locomotives, with cylinders ranging from 17 to 21 ins. diameter, give the following rule :—

$$d = 0{\cdot}375C + 1$$

d being the diameter of main bearings and C the diameter of cylinders.

The crank-pin journals are usually the same diameter as the main bearings, the barrel or centre portion about ¼ in. less and the wheel seat 1 in. more. Thickness of webs varies from 4 to 4½ ins.

Built-up crank axles are common. The advantages over a forged axle are cheapness, more effective bearing surfaces due to absence of radii, fractured parts may be replaced without scrapping the whole axle. By extending the webs a balanced axle is obtained. Special steels may be used.

BEARING SURFACES.

Inside main bearings should be so proportioned that the pressure per square inch of diametral area does not exceed about 250 to 260 lbs. (*Wolff.*)

For crank-pin journals and coupling-rod pins, the pressure may be as much as 1,500 lbs. per sq. in., the load on connecting rod being taken as full boiler pressure on piston area.

For crosshead pins 4,000 lbs. per sq. in. is allowable on account of the small angular movement. Crosshead slippers should be about 60 lbs. per sq. in., a low pressure being advisable on account of the exposure of slide bars to sand and grit.

WHEELS AND TYRES.

Cast-steel wheels are general. The method of securing tyres by means of set screws through the rim of wheel is the most common. The alternative is to depend on the shrinkage of the tyre to grip the wheel, a retaining ring being inserted to lock the tyre in place laterally. This is a cheap and satisfactory fastening, but there is a tendency for tyres to become loose as they wear thin.

The shrinkage allowance for tyres is usually between 1/750th and 1/1000th of the diameter of wheel centre.

Driving wheels have tyres with flanges about $\frac{3}{16}$ in. thinner than the other wheels. This eases the engine on curves and protects the crank axle to some extent. Blind or flangeless tyres are uncommon in England, although often resorted to in America.

Of modern types the 4–4–0 engine is the most economical in tyre wear. The flanges of the leading bogie wheels which guide the engine wear much faster than the second pair. Bogie wheels wear less than radial truck wheels, as a bogie sets itself tangentially to any curve. In engines of the 0–6–0 and 0–8–0 types mileage is determined by the flange wear of the leading coupled wheels.

Tyres with treads worn hollow are detrimental to points and crossings. A flange worn sharp is liable to cause derailment. Tyres are turned down to 1$\frac{5}{8}$ ins. on tread and allowed to wear to 1$\frac{1}{2}$ ins. before they are scrapped.

Wheels are forced on axles by hydraulic pressure. A minimum of 10 tons per inch diameter of wheel seat should be allowed when rape oil is used as a lubricant, 100 tons being a usual amount for large axles; or, if D is the diameter of wheel seat in inches, the load = 10D tons.

The wheel is bored slightly less in diameter than the axle, the difference expressed as a fraction of an inch being from $\frac{2D + 3{\cdot}5}{1{,}000}$ to $\frac{4D + 2}{1{,}000}$, depending on rigidity of the boss, quality of steel, etc.

Crank pins should be forced in with a minimum pressure of 13 tons for each inch of diameter, and the ends of the pins riveted over inside the wheels.

FLEXIBLE WHEEL BASE.

Main-line engines should be capable of traversing a curve of 5 chains rad us, and sufficient side-play is given to bogies and radial wheels for this. The theoretical amount required is not attained in practice, as engine frames and track spring a little on sharp curves.

There is a small amount of side-play allowed between flanges of wheel and rail. With new tyres on new rails, this is about $\frac{3}{16}$ in. each side, or a total of $\frac{3}{8}$ in. The flanges of driving wheels are thinned down to give double this amount, about $\frac{3}{4}$ in. total. Additional side-play is sometimes given by allowing a little clearance between axle-boxes and guides. It is very exceptional to give any side-play between journal and bearings.

Baldry's rule for the radius of pony trucks is

$$R = \tfrac{1}{2}\left(B - \frac{A^2}{B}\right),$$

where B is horizontal distance from truck wheels to centre of rigid wheel base and A is half rigid wheel base.

Bogies, in addition to turning on the pin, are allowed a certain amount of transverse movement. This is controlled by springs, suspension links, or inclined slides. Bogies on the L. & N.W.R. and N.E.R. have curved slides giving radial instead of transverse movement. Fixed centre bogies are now but little used.

Counterbalancing Locomotive Driving Wheels.

The revolving and about 60 per cent. (this figure varies considerably) of the reciprocating parts should be counterbalanced. The revolving parts develop centrifugal force, the horizontal component of which disturbs the engine longitudinally, to which must be added that due to the momentum of the reciprocating parts: also, these two forces produce a sinuous motion by acting first upon one side of the engine and then on the other. The vertical component of the centrifugal force generates a rolling motion by acting alternately upon each side of the engine. A peculiar effect is also produced by the obliquity of the connecting-rod to the slide bars, a turning upon a horizontal axis, together with an up-and-down movement at the crank axle. The horizontal forces are the most injurious, although some American engineers consider the vertical to be so; but English practice is to take a medium course between excessive horizontal and vertical disturbing influences. It has been clearly demonstrated that high centres of gravity are advantageous.

When of outside type, balance the balance weight by means of the moving parts on one side and a small weight, at the same angle from the balance weight, in the far wheel.

For inside cylinder engines place a balance weight in each wheel inversely proportional to the distance from the cylinder and diametrically opposite the crank. Thus there are two counterweights in each wheel, but these are combined to form a single balance weight, usually of crescent shape.

American practice is to allow 1/400th part of the engine weight to remain unbalanced in the reciprocating parts on each side. The remainder is then divided amongst the coupled wheels; or

$$r = \frac{R - \frac{W}{400}}{N},$$

where r = reciprocating weight in each wheel at crank pin radius R = total weight of reciprocating parts, W = weight of engine in working order, and N the number of coupled axles.

Cast steel wheels have the balance weights cast solid with them; occasionally the weights have pockets cored out for the reception of lead. Another practice is to cast the wheels without weights and to rivet steel plates to the spokes. Molten lead is then run into the pockets formed between the spokes.

In order to obtain uniformity of results, some railways make use of a wheel-balancing machine. The pair of wheels to be tested is mounted on bearings supported by springs set radially round them. Weights are attached to the crank pins to represent the revolving and a proportion of the reciprocating parts. The wheels are then spun round at high speed and the counterbalance adjusted until steady running is obtained.

BOILERS.

Grate Area and Heating Surface.

Grate area in square feet $= \frac{\text{average I.H.P.}}{30}$. Total heating surface should be not less than 60 × grate area, and at least 10 per cent. of this should be in fire-box.

The ratios giving the best results are as follows:—Grate to total heating surface, 1 : 55 to 65; grate to fire-box heating surface, 1 : 5 to 5·5; and fire-box heating surface to total heating surface, 1 : 11 to 12. In some comparative trials made between British and American locomotives, the extra length of the American grates was considered a disadvantage; 8 ft. is the greatest length of grate that can be efficiently fired by hand. (*G. E. Jones.*)

Approximately, 1 h.p. can be obtained from each 2½ square feet of heating surface. (*Lawford H. Fry.*)

Bituminous coals require space in the fire-box for the proper combustion of their gases before entering tubes. The fire-box volume should be 6 or 7 cubic feet for every square foot of grate. Under these conditions 15 lbs. of air are needed for each pound of coal burnt. The air spaces through fire-bars should not be less than 35 per cent. of grate area, and the damper opening not less than 15 per cent. Air spaces of 50 per cent. and damper opening 20 per cent. are not too large. In coupled engines, where an axle comes close under the grate the slope of pan over it should be not less than 45°; and the restricted space for air between pan and fire-bars must have an area of at least 15 per cent. of the part of the grate which it supplies.

Boiler Tubes.

Ratio of diameter of tubes to length.—Continental Compound, 60; American Express, 70; English Express, 75; six-wheeled coupled Continental Express, 80.

Thickness of locomotive boiler tubes (Caledonian Railway), 5-in. tubes, No. 8 W.G.; 1¾-in. tubes, No. 11 W.G.

Water space between tubes should not be less than ⅝ in.

Life of Boiler Tubes.

The life of copper and steel tubes in locomotive boilers, taken over a period of eight years is as follows:—

	Miles.
Copper 1st period (new)	110,000
„ 2nd period (drawn)	80,000
„ 3rd period (pieced)	50,000
Total	240,000

Subsequently 30 to 40 per cent. of those pieced are treated so again.

	Miles.
Steel 1st period (new)	70,000 to 80,000
„ 2nd period (pieced)	30,000 to 40,000

(*G. Hughes.*)

Calculation of the Heating Surface of Boilers for Locomotives.

The Associa ion of Railway Locomotive Engineers' method of calculating the heating surfaces of locomotives is as follows :—

Fire-box.—The outside (wetted surface) of inner fire-box plates to be taken to top of foundation ring. Areas of tube-holes and sectional area to wetted side of fire-hole ring, or flanged plate, as the case may be, to be deducted ; section of fire-hole being taken close up to the inner fire-box plate.

No deductions to be made for copper stays or roof stays. If the boiler has fire-box water tubes the surface to be taken on the inside (wet side) of tube.

Tubes.—The outside surface of tubes (wet side) to be taken, calculated on uniform diameters for both ordinary and superheater tubes ; the length of tube being taken between tube-plates.

Elements.—The inside surface (steam side) of elements to be taken, the effective length of tube being from and to smoke-box end of large flue tube.

Smoke-box tube-plate.—No allowance to be made.

Fire-Boxes.

Many attempts have been made to substitute steel for copper plates in fire-boxes of British locomotives, but the results have not been very successful. Steel fire-boxes are universal in America, where conditions favour their adoption. Greater success had attended the introduction of steel side stays for copper fire-boxes. Owing to the higher tensile strength the diameter over threads is about $\frac{5}{8}$ in. for a pitch of $3\frac{1}{2}$ ins. The stay projects through the fire-box casing plate about $\frac{1}{4}$ in., but the projection through the copper plate is furnished with a hexagon nut of reduced thickness. This forms a renewable head for the stay and protects it from injury by the fire.

In locomotive practice a pitch of about 4 ins. is almost invariably adopted for the screwed stud stays in the fire-box. Theoretically this is much closer than is necessary, but the practice is good, as it provides a substantial margin of wear in the copper plates.

Life of Fire-Boxes.

The life of fire-boxes depends more upon the tons hauled than the actual miles run. Copper fire-boxes on the Lancashire and Yorkshire Railway have a life of from 10 to $16\frac{1}{2}$ years. The older engines with 140 lbs. pressure are found to run their fire-boxes up to as much as 500,000 miles : an average figure for 70 engines being 310,000 before replacement by new ones. In standard engines, such as the radial tank and 6-wheeled coupled goods classes, working at 160 lbs. pressure, the average life of a copper fire-box is eleven years, with average mileages of 272,000 and 235,000 respectively. These figures are based upon records of 120 locomotives. Individual copper tube-plates in the fire-boxes above named require renewing during the life of the box. In the radial tank class, records of 53 tube-plates show an average life of seven and three-quarter years with 205,000 miles before renewing, whilst the 6-wheeled goods average 135,000 miles for 144 tube-plates. The remaining plates, viz., door and wrapper plates, practically do not require replacing during the life of the fire-box, but certain repairs and patches are fitted if necessary.

Superheaters.

Steam superheating in the case of locomotive engines may be described as ' two-stage steam generation.' The volumetric increase obtained by superheating enables larger cylinders to be used, or steam pressures to be reduced. The management of a superheater locomotive is usually a little different from that of a saturated steam engine, owing to the fact that each driver has given work to do, and he controls his engine with that end in view having regard to the design and equipment under his charge.

Fire-tube Superheaters are principally employed. Several rows of large fire tubes are fitted in the boiler, and into these superheating tubes extend from a header or headers in the smoke-box towards the fire-box and back again. The construction of the header varies, as well as the arrangement of tubes, but the object in all designs is to direct steam through small tubes exposed to hot gases direct from the furnace and supplying an extended steam path, so that while travelling at a high velocity a considerable degree of heat is taken up by the steam.

The Swindon (used mainly on the Great Western Railway) and Vaughan-Horsey (employed principally in Canada) designs are of this class, with their own constructional features, and both are designed for a moderate degree of superheat. The Schmidt design aims at a high superheat—from 200°–300° F. It is used with a four-fold arrangement, as shown in fig. 9 (page 598). This provides a long steam path, so that, notwithstanding the high velocity of the steam, it is able to take up the required heat. A special feature of the Schmidt apparatus is the simple flange device by which the elements are connected to the header. This arrangement enables a damaged element to be easily replaced or a blank flange fitted for the time being.

In conjunction with some fire-tube superheaters a damper mechanism operated by an automatic steam cylinder is fitted so that the passage of furnace gases through the apparatus may be prevented when steam is not being used. In some cases this is hand operated, and on the Midland Railway Sir Henry Fowler has fitted to goods engines a device whereby the dampers can, if desired, be kept open so that during shunting, and like operations, superheat can be maintained.

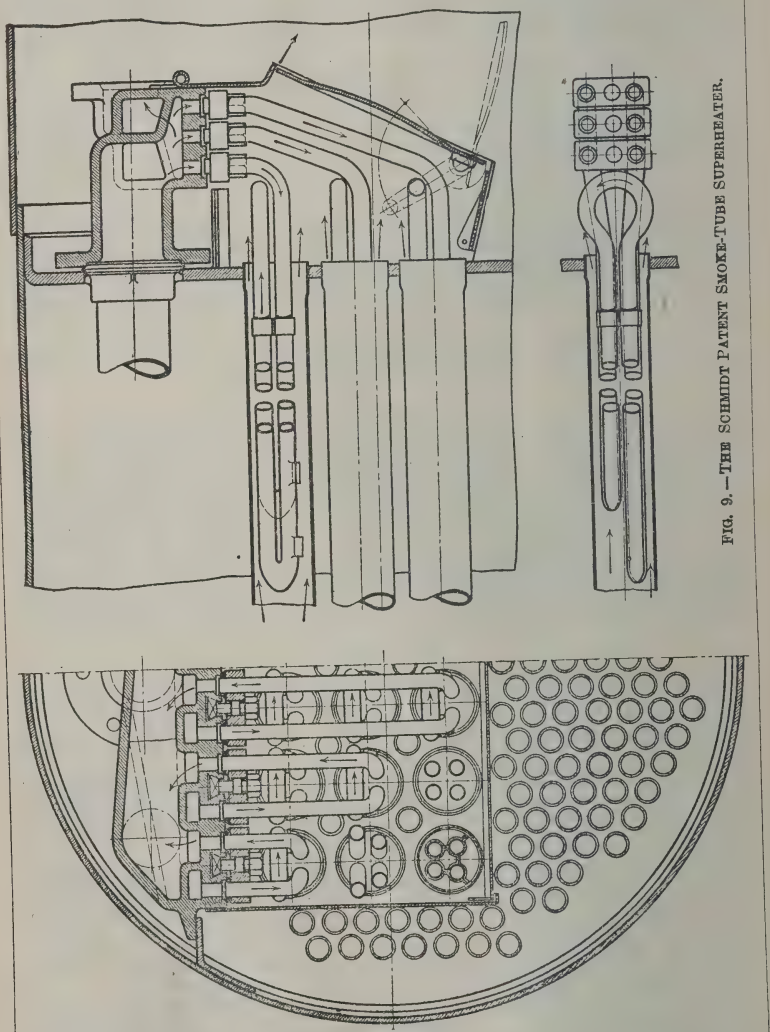

FIG. 9.—THE SCHMIDT PATENT SMOKE-TUBE SUPERHEATER.

Instead of a damper or draught retarder, some railways, such as the G.N.R., G.E.R., and S.E. & C.R., fit snifting or anti-vacuum valves on the top of the smoke-box. When an engine is drifting with steam shut off air is drawn from the valves through the superheater elements and prevents overheating. At the same time the air is heated before coming into contact with the valves and thus reduces the risk of the valve liners becoming loose by contraction from sudden cooling.

The Robinson Superheater.

Two types of superheaters have been designed, type 'A' having a header or steam collector with transverse compartments and a removable front cover plate, and type 'B' having a header or steam collector with two longitudinal compartments and removable top covers.

Type 'A.'

The transverse compartment superheater with removable front cover, fig. 10 (page 600), is composed of a number of cold drawn mild steel pipes (A) manufactured from best Swedish steel billets, and a header or steam collector (B) into the bottom of which the ends of the superheating pipes are expanded at (b). In applying this superheater to a locomotive type boiler the header or steam collector (B) is connected by a flange (C) to the main saturated steam pipe (D), leading from the dome, immediately above and perfectly clear of the smoke or flue tubes in the smoke-box tube plate (E). The header is divided into a number of separate transverse compartments, several of which (F) receive and distribute the saturated steam from the main saturated steam pipe to the superheating pipes, and the remainder of these compartments (G) receive the superheated steam from the superheating pipes and distribute the same to the steam pipes (H) leading to the steam chests of the engine cylinders.

The superheated and saturated steam compartments (GF) are open at the front of the header to permit of the header being examined internally and for the introduction of the tube expanders into the ends of the superheating pipes (A) for expanding the same into holes in the bottom of the header. The superheating pipes are also readily disconnected from the header by means of suitable tools which are inserted through the front of the header.

The front of the header is made steam tight by means of a cover plate (I) secured with a number of studs and nuts. The bottom of the header or collector (B), which forms the tube plate into which the ends of the superheating pipes are expanded, lies parallel to and above the top row of smoke or flue tubes. A number of the smoke or flue tubes (J) are of large diameter to receive the superheating pipes (A); these pipes leave the header (B) vertically until they come opposite the large flue tubes (J), when they are bent at right angles and extended into the smoke or flue tubes (J). Each superheating pipe or element (A) consists of four lengths of pipe extending nearly the whole length of the large smoke or flue tubes (J), the ends of each length of pipe being suitably connected at (K).

Type 'B.'

In this type (fig. 11, page 600) the header or steam collector is divided into two longitudinal compartments A and B, the former receiving the saturated steam from the boiler and distributing the same to the superheating pipes, and the latter receiving the superheated steam from the superheating pipes and distributing the same to the steam pipes leading to the steam chests. The saturated and superheated steam compartments A and B are open at the top of the header to permit of the header being examined internally and for the expanding of the superheating pipes into position. The superheating pipes can be readily disconnected from the header, should this be necessary.

The top of the header is made steam tight by means of cover plates C secured by studs and nuts. Each superheating pipe or element consists, as usual, of four lengths of pipe extending nearly the whole length of each large smoke or flue tube, the ends of each length of pipe being suitably connected.

With this design of superheater the superheating pipes are so arranged that any particular element can be withdrawn and replaced without disturbing any other element.

With the type 'B' header, insufficient headroom in the smoke-box will in many cases necessitate the provision of removable covers in the smoke-box shell, immediately above the header, to admit of accessibility to the superheating pipes. These covers however would be comparatively small. As the superheating pipes are expanded directly into the header, no attention to joints is necessary, and it would only be in the event of the renewal of an element or of a large flue tube that it would be necessary to remove the cover.

Statistics in regard to the Robinson superheater are said to show an average saving in coal and water consumption, and in boiler repairs, of 25, 30, and 25 per cent., respectively.

The Robinson Draught Retarder.

The draught retarder (for the prevention of overheating of the elements when the steam is shut off at the regulator) consists of a number of small steam nozzles disposed in the smoke-box, one nozzle extending a short distance into the smoke box end of each large superheater smoke tube. The nozzles are connected to the pipe which supplies steam to the blower so that when the latter is turned on, the jet of steam delivered from each nozzle is just sufficient to neutralise the forward draught induced by the blower. This draught retarder obviates the necessity for fitting any form of mechanical damper inside the smoke-box.

THE ROBINSON SUPERHEATER.

The WEIR FEED HEATER & FEED PUMP for LOCOMOTIVES

The simplest, most efficient and reliable system yet introduced

Waste steam effectively utilised and feeding troubles eliminated. Certainty of action under all conditions, great range of feeding capacity and improved tractive power ensured.

Hundreds of successful installations in service on many of the most modern Locomotives.

Detailed Particulars on Application.

G. & J. WEIR Ltd. CATHCART GLASGOW

F. 601

The Sugden Superheater.

(*T. Sugden, Ltd.*, 180 *Fleet Street, London, E.C.* 4.)

These superheaters are of the smoke-tube type, and are made in two principal designs.

In design 'A' the superheaters are constructed of mild steel throughout, and consist of two separate headers fixed near the top of the smoke-box, and connected directly to tube elements which pass forward into the smoke-tubes of the boiler.

One header is connected to the saturated steam supply, and the second header receives the steam after it has passed through the superheater elements.

The elements are of the usual spear-head type, and are formed from solid drawn mild steel tube, and are connected to the headers by flanged joints of special construction with through bolts passing from the top to the bottom of the header.

In the 'B' type superheater the main header is of cast steel and divided into two compartments, one compartment supplying the saturated steam and the other being used for receiving the superheated steam from the tube elements.

A number of sectional headers are connected to the main header, and pass down in front of the tube plate between the smoke-tubes; one-half of the sectional headers supplies saturated steam to the tubular elements, and other sectional headers receive the superheated steam.

The tubular elements are again of spear-head type, and are connected to the sectional headers by expanded joints, and can be re-expanded or stopped by plugs through access covers which are provided in front of the sectional headers.

The Weir System of Boiler Feeding and Feedwater Heating.

In this system, fig. 12 (page 602), the boiler feeding is carried out by means of a direct-acting steam pump, B. The discharge side of the pump is connected through J to a surface heater, A, of special design. The heater is arranged in any convenient position on the locomotive, and uses part of the exhaust steam from the blast pipe, this steam passing to A through a pipe, D, which is teed off from the blast pipe. The heating steam impinges on the outside of the heater tubes. The orifice of the blast pipe is not altered in fitting the heater connection, so that the effective exhaust area is substantially increased with consequent reduction in back pressure on the engine.

The pump, B, has double acting steam and water cylinders. The suction and delivery valves for both ends of the water cylinder are arranged within the casing in front of the pump. Steam to the cylinder passes through H, and is controlled by a Weir piston valve chest. No drain valves are provided on the steam cylinder, as the pump will start from cold, even with the cylinder full of water of condensation. Plugs are fitted, however, on the steam cylinder, the steam valve chest, the water valve chest, and the pump cylinder, and may be utilised when it is considered necessary to empty the system.

While the vertical type of pump is usually adopted special circumstances may arise in which the use of a horizontal type is more convenient; and to meet these cases the larger sizes of pumps are designed on the horizontal pattern.

In the design of the heater, strength and simplicity with ready facilities for inspection are special features. A cylindrical shell of cast iron forms the steam space, with branches for the admission of the exhaust steam, and a connection for draining the condensed water. The tube plates are fixed to the ends of the shell by collar bolts, which also carry the end covers. The latter are provided with ribs which divert the feed water through the various passes of the heater. The tubes are of heavy solid drawn copper, and are so expanded into the tube plates that they form strong and reliable joints under all conditions.

The feed water, after traversing the heater tubes, passes through G directly into the steam space, through a special spraying valve, C, situated on the top of the boiler. By this means the feed water reaches the water surface in the boiler at practically the steam temperature, and secures increased efficiency and decreased upkeep of the boiler, due to the uniformity of temperature maintained. Where chalky waters are in use, the heating of the feed water to the steam temperature has also a pronounced effect on the character of the deposit; this takes the form of a fine sludge, which may be readily washed out. Both pump and heater are of neat and compact design, the installation occupies very little space and is in no way obtrusive on the locomotive. The fitting of the gear is, moreover, simple, as it involves no serious alterations in design or structure.

It is claimed that by the system, with feed water temperatures below 60° F. in the tender, and with any type of locomotive, saturated or superheated, a definite fuel economy of not less than 10 per cent. for the same locomotive duty is obtained, or for the same fuel consumption an increase of 10 per cent. in the evaporative power of the boiler; the feed pump gives a degree of feed flexibility and reliability which is not obtainable with injector feeding.

Hulburd's Seamless Soft Copper Jointings.

These patent jointings are absolutely seamless, being cut from the solid plate and machined all over. They are produced by a special process which provides the greatest strength combined with softness of which copper is capable. They are made in a variety of sections to meet different requirements, and of any size and shape. The special advantages they offer are that hand-scraping of joint faces is rendered unnecessary, no red or white lead fillings are required, the joint being absolutely metal to metal; joints made with them may be broken as often as desired

THE WEIR SYSTEM OF BOILER FEEDING AND FEEDWATER HEATING.

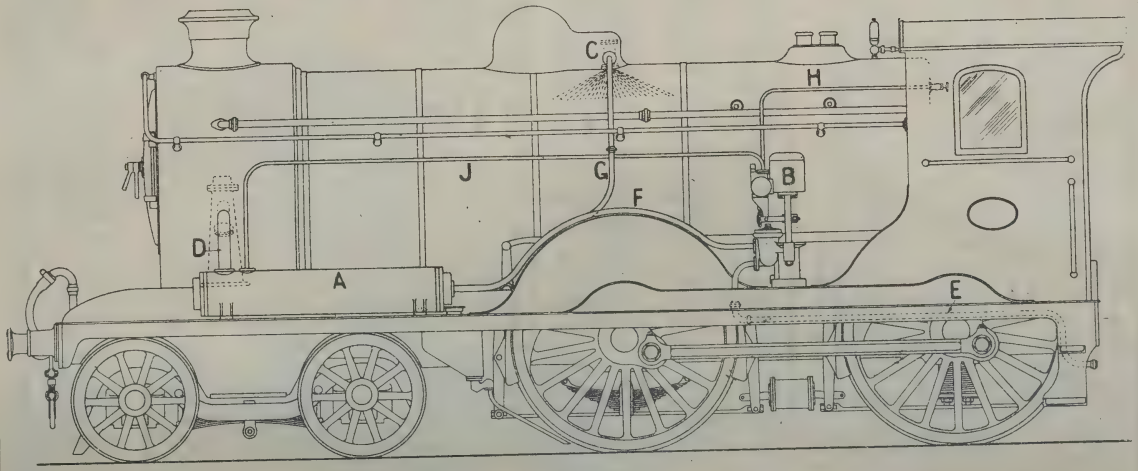

FIG. 12.

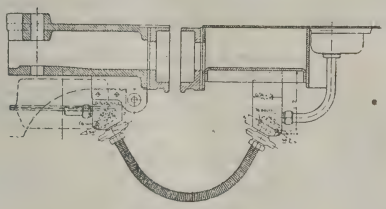

FIG. 13.—Feed Water Connection.

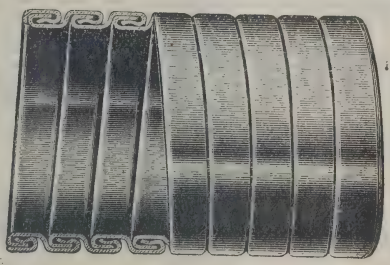

FIG. 14.—Section of Flexible Metallic Tubing.
(*United Flexible Metallic Tubing Co. Ltd.*)

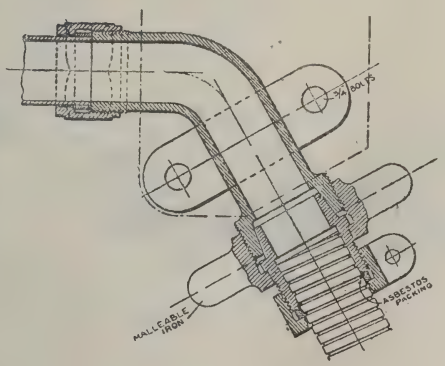

FIG. 15.—'Ball and Socket' Joint.

without the use of tools, and they may be used over and over again. Cases are known in which the same jointing has been used as many as eighteen times. The strength of the jointings is such that they may be used for pressures up to 2,000 lbs. per square inch. They are largely employed for locomotives—especially for domes, cylinder covers, and steam chests—by most of the leading railways and are supplied to nearly all the ships of the Navy. No single case of failure has ever been reported.

Flexible Metallic Tubing.

On the locomotive, an essential fitting is the feed-water connection between the engine and the tender, fig. 13 (page 603), this connection allowing any surplus steam from the boiler to be used to heat the feed water in the tender. Fig. 14 shows Flexible Metallic Tubing (*The United Flexible Metallic Tubing Co.*) which is specially suitable for the purpose, as rubber connections will not withstand the heat.

Flexible Metallic Tubing is also used for carriage heating, and being much stronger and lighter than rubber hose it will stand the full boiler pressure if the reducing valve fails, the pressure at the carriages being only about 40 lbs., whereas the boiler pressure is probably 200 lbs. The tubing when exposed to cold is in no way affected, even should any accumulation of water in the pipes be frozen solid.

With this Flexible Metallic Tubing there is no possibility of the drain valves of the couplings being stopped up by anything wearing or blowing off the interior of the tubes.

The 'Ball and Socket' joint, fig. 15 (designed by the locomotive engineer of the Lancashire and Yorkshire Railway), when fitted to the tubing, gives great flexibility. The asbestos ring, upon which the 'ball' rests in a measure, allows the ball joint to be flexible when under steam pressure.

The tubing is manufactured in various lengths, and in sizes from ¼ in. to 12 ins. internal diameter, and to resist pressures from 20 lbs. to 4,000 lbs. per sq. in.; it has been largely used in the place of rubber hose on account of its great strength, flexibility at all temperatures, non-liability to the attacks of vermin or insects, and that it remains indestructible by great heat, oils, or grease.

Flexible Metallic Tubing is specially suitable for tropical climates, as the sun's rays have no effect upon it, whether 'in stock' or in use.

Injectors.

Metcalfe's Patent Exhaust Steam Injector.

The simplest method of using exhaust steam for feed water heating is by an exhaust steam injector. A saving of 10 to 15 per cent. of coal, and 12 to 15 per cent. of water, is claimed.

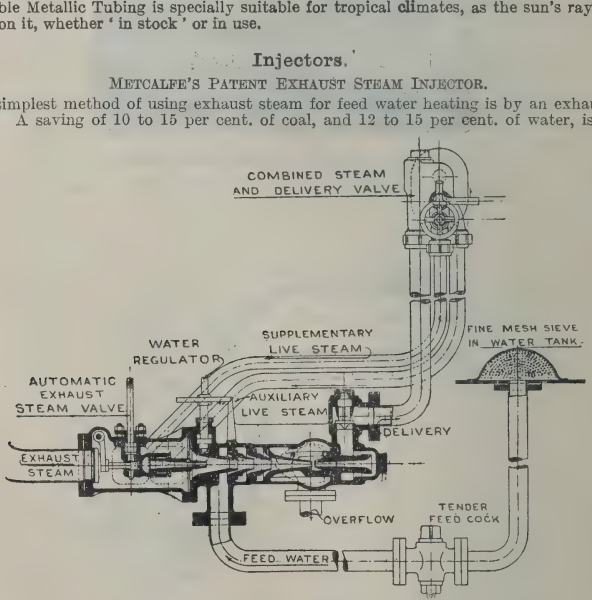

Fig. 16.—'Metcalfe' Patent Exhaust Injector (F. Type).

The latest type 'F' Metcalfe Patent Exhaust Injector is capable of working on exhaust steam alone against boiler pressures up to 150 lbs. per sq. in., and with the aid of a small jet of supplementary live steam it can feed against 300 lbs. pressure. The temperature of feed water delivered

to boiler varies from 200° to 220° F., depending on exhaust steam pressure. The amount of supplementary live steam is very small and does not exceed 2½ per cent. of evaporation of boiler. The water regulator, which slides the cone, can be adjusted so that the injector is kept continuously at work throughout the run, and will maintain a constant water level and steam pressure. By the introduction of very hot feed water the steaming power of the boiler is extended and the stresses in the plates, due to unequal contraction, are reduced. When the engine regulator is shut and the flow of exhaust steam ceases, the injector can be kept at work by the admission of a small quantity of live steam to take its place : this is termed auxiliary steam. The exhaust steam is conveyed from the cylinders to the injector by means of a large pipe. After leaving the cylinders the steam passes through a simple form of grease separator, consisting of a sleeve covered with Turkish towelling. Greasy water is discharged through an automatic drip valve.

A size 10 injector will deliver a maximum of 2,300 gallons of water per hour, and this can be reduced by the water regulator to a minimum of 1,380 gallons per hour (working continuously).

Gresham's Patent Hot Water Combination Injector.

These injectors, Fig. 17, work with either hot or cold water in the usual way, *i.e.* by opening the steam valve and water cock, and then regulating the water cock if necessary.

An internal steam pipe from the dome of the locomotive conveys steam to the injector steam valve A, which, being opened, admits steam to the steam nozzle 1 by the passage B. The steam

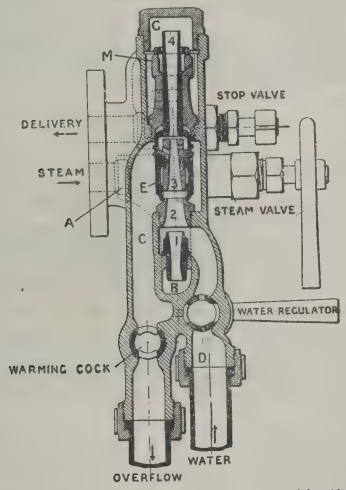

Fig. 17.—'Gresham' Patent Hot Water Combination Injector.

issuing from the steam nozzle opens the two side flaps E ; it also lifts the sliding delivery cone 4 making an aperture at M and passes out freely down the overflow pipe. In doing so it creates a partial vacuum in the water pipe D, and the water rises to the injector. The water then coming in contact with the steam travels with it through the lifting cone 2, and, in condensing, it creates a vacuum which closes the two side flaps E, thus preventing any air entering the cones. The velocity of the steam being now largely transferred to the water, the latter passes from the lifting cone 2 through the combining cone 3. After passing through this combining cone, the jet flows out of the aperture M and down the overflow pipe C until such time as it attains sufficient velocity to carry itself past this space and enter the delivery cone 4. When it reaches this point the jet is at its maximum velocity, and is so great that it is sufficiently powerful to lift the back pressure valve (not shown) and so enter the boiler. At the same time the pressure thus created in the chamber G forces the sliding delivery cone down on to its seat and closes the aperture M, shutting in the water which otherwise would be boiled off when the injector is working with water at 130° F. When the water is below 100° F. the injector will work dry with the aperture M open, like an ordinary injector.

In order to heat the feed water, exhaust steam is conducted from the cylinders to the tender by a large pipe. This connects to a multi-tubular heater through which the feed water flows. The condensation of the steam gives up heat which is absorbed by the feed water, thereby raising its temperature.

BRITISH STANDARD SPECIFICATIONS FOR MATERIAL USED IN THE CONSTRUCTION OF RAILWAY ROLLING STOCK.*

(Report No. 24—1921.) (*Abstract.*)

Locomotive Crank Axles—B.S.S. 1.

The crank axles shall be manufactured from the highest quality of steel made from the best selected material by the acid open-hearth process. On analysis, the steel must not show more than ·04 per cent. of sulphur or of phosphorus.

The metal must show a tensile breaking strength of not less than 32 tons per square inch, with an elongation of not less than 22 per cent. on Standard Test Piece C or D. The yield point in either case must be not less than 50 per cent. of the ultimate tensile strength.

A test piece 9 ins. long and 1¼ in. square, with $\frac{1}{10}$ in. radius at the edges, machined from each crank axle, must withstand being bent cold by direct pressure from a tool 2 ins. wide, the end having a radius of 1 in., until the sides of the test piece are parallel. The ends of the test-piece are then to be brought together without fracture, by direct pressure.

As an alternative to the cold bend test, the test piece may be placed upon bearings having a clear span of 6 ins., resting on a solid foundation, and must withstand, without fracture, 20 blows from a weight of 1,120 lbs., having a rounded end of 1¼ in. radius, falling 6 ins. The test piece shall be reversed after the first and every alternate blow. The fall shall then be increased to 12 ins., and the test continued until fracture occurs. Crank axles having flat or oval webs, test pieces to be taken from between webs. Crank axles having round webs, test pieces to be taken from end of axle.

All crank axles shall be either normalised or oil-treated.

Locomotive Straight Axles—B.S.S. 2.

Quality of material same as for locomotive crank axles, except that steel must not show more than ·05 per cent. of sulphur or phorphorus.

The axle shall be placed upon bearings resting on a block of metal of not less than 5 tons weight supported on a rigid concrete or other solid foundation, and must withstand, without fracture, 5 blows from a weight of 2,240 lbs., falling 16 to 35 feet, according as the diameter is under 4 or over 6 ins., the distance apart of the bearings being from 3 ft. to 5 ft.

The axle shall be turned after the first and third blow, and shall be broken after testing, both in the centre and at the journals.

The metal must show a tensile breaking strength of 35 to 40 tons per square inch, with an elongation on Standard Test Piece C or D of not less than 25 per cent. with 35 tons, and 20 per cent. with 40 tons; the sums of the intermediate tensile breaking strengths and corresponding elongations being not less than 60. The yield point must be not less than 50 per cent. of the ultimate tensile strength.

A test-piece 9 ins. long and 1¼ in, square, with $\frac{1}{16}$ in. radius at the corners, must withstand being bent cold by direct pressure from a tool 2 ins. wide, the end having a radius of 1 in., until the sides of the test piece are parallel. The ends of the test-piece are then to be brought together without fracture, by direct pressure.

N.B.—This test taken only when less number than 15 axles are ordered and falling weight test has not been carried out.

All axles shall be either normalised or oil-treated.

Locomotive Straight Axles—B.S.S. 2A.

The axles shall be manufactured from the highest quality of steel made from the best selected material by the acid or basic open-hearth or acid Bessemer process. In the event of the basic hearth process being employed, the maximum percentage of sulphur and phosphorus must not exceed ·05 per cent. The tests are the same as previous specification.

Carriage and Waggon Axles—B.S.S. 3, B.S.S. 3A.

Same as for locomotive straight axles (B.S.S. 2 and B.S.S. 2A), except that range of falling weight test is from 15 to 30 ft. for axles under 3¾ ins. to over 6 ins.

---

* By permission of the British Engineering Standards Association.

Locomotive Tyres—B.S.S. 4.

Quality of material same as for locomotive straight axles—B.S.S. 2.

The tyre shall be placed in a running position with the tread resting on a block of metal of not less than 5 tons weight supported on a rigid concrete or other solid foundation, and must withstand, without fracture, blows from a falling weight of 2,240 lbs. The weight shall be allowed to fall freely on to the tread from heights of 10 ft., 15 ft., 20 ft., and upwards, until the deflection of the tyre corresponds to that given in the following formula, in which d is the internal diameter of the tyre as rolled, in inches, and t is the thickness of the centre of the tread, as rolled, in inches. For tyres having an inside snip exceeding $1\frac{1}{4}$ ins. in depth, the calculated deflection shall be reduced by 5 per cent., and for tyres having an inside snip exceeding $1\frac{1}{2}$ ins. in depth, by 10 per cent.

Class C.—Tensile Breaking Strength 50 to 55 tons per square inch, and minimum elongation 13 to 11 per cent. (Standard Test Piece C).	Class D.—Tensile Breaking Strength 56 to 62 tons per square inch, and minimum elongation 10 to 8 per cent. (Standard Test Piece C).	Class E.—Tensile Breaking Strength 63 to 69 tons per square inch, and minimum elongation 10 to 8 per cent. (Standard Test Piece C).
$\frac{d^2}{50\,t^2}$	$\frac{d^2}{55\,t^2}$	$\frac{d^2}{60\,t^2}$

When so specified in the inquiry each tyre shall be allowed to drop freely in a running position, from the height specified below, upon a rail fastened to an iron block of not less than 2 tons in weight. Each tyre shall then be turned round through an angle of 90 degrees, and dropped a second time.

Internal diameter of tyre.	Up to $3\frac{1}{2}$ ft.	Over $3\frac{1}{2}$ ft. and up to $4\frac{1}{2}$ ft.	Over $4\frac{1}{2}$ ft. and up to $5\frac{1}{2}$ ft.	Over $5\frac{1}{2}$ ft. and up to $6\frac{1}{2}$ ft.	Over $6\frac{1}{2}$ ft.
Height of fall	5 ft.	4 ft.	3 ft. 6 ins.	3 ft.	2 ft. 6 ins.

Carriage and Waggon Tyres—B.S.S. 5.

The specification is the same as for locomotive tyres, with the addition of Class B tyres, tensile breaking strength 42 to 48 tons per sq. in. and minimum elongation 18 to 15 per cent.

Formula for deflection $\frac{d^2}{45\,t^2}$.

Carriage and Waggon Tyres—B.S.S. 5A.

Material same as locomotive straight axles—B.S.S. 2A. Otherwise same as carriage and waggon tyres—B.S.S. 5—except that Class E is omitted.

Laminated Springs—B.S.S. 6.

The spring plates shall be manufactured from the highest quality of steel made from the best selected material by the acid open-hearth process. The steel must not show more than ·8 per cent. nor less than ·5 per cent. of carbon, nor more than ·05 per cent. of sulphur or of phosphorus. The steel for the top plates, which have to be welded at the eye, must not contain more than ·7 per cent. nor less than ·45 per cent. of carbon.

All finished springs shall be tested by being deflected by a quick-acting scrag before the buckle is put on, to an amount equal to $\frac{L^2}{900t}$, where L is the length of the top plate in inches measured along the arc as shown in fig. 18, and is the thickness of the thickest plate in inches They must then stand being deflected again three times in quick succession without showing any permanent set. The required deflections are shown in the table and must not be exceeded at any time during manufacture by more than 15 per cent.

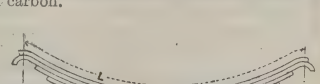

Fig. 18.

All plates shall be carefully hardened and tempered.

The buckles shall be made of good fibrous iron having a tensile breaking strength of from 20 to 24 tons per square inch, or of suitable steel having a tensile breaking strength of not more than 24 to 30 tons per square inch. The elongation in each case shall be not less than 20 per

L	Required Deflection under Scrag, in Inches.				
Ins.	$\frac{3}{8}$ in. plate.	$\frac{7}{16}$ in. plate	$\frac{1}{2}$ in. plate.	$\frac{9}{16}$ in. plate.	$\frac{5}{8}$ in. plate.

84	$20\frac{7}{8}$	$17\frac{7}{8}$	$15\frac{5}{8}$	14	$12\frac{1}{2}$
78	18	$15\frac{1}{2}$	$13\frac{1}{2}$	12	$10\frac{7}{8}$
72	$15\frac{3}{8}$	$13\frac{1}{4}$	$11\frac{1}{2}$	$10\frac{1}{4}$	$9\frac{1}{4}$
66	$12\frac{7}{8}$	11	$9\frac{5}{8}$	$8\frac{5}{8}$	$7\frac{3}{4}$
60	$10\frac{5}{8}$	$9\frac{1}{8}$	8	$7\frac{1}{8}$	$6\frac{3}{8}$
54	$8\frac{3}{8}$	$7\frac{3}{8}$	$6\frac{1}{4}$	$5\frac{3}{4}$	$5\frac{1}{8}$
48	$6\frac{3}{4}$	$5\frac{5}{8}$	$5\frac{1}{8}$	$4\frac{1}{2}$	$4\frac{1}{8}$
42	$5\frac{1}{4}$	$4\frac{1}{2}$	$3\frac{7}{8}$	$3\frac{1}{2}$	$3\frac{1}{8}$
36	$3\frac{7}{8}$	$3\frac{1}{4}$	$2\frac{7}{8}$	$2\frac{1}{2}$	$2\frac{1}{4}$
30	$2\frac{3}{8}$	$2\frac{1}{4}$	2	$1\frac{3}{4}$	$1\frac{5}{8}$

cent. (Standard Test Piece A), and the material must admit of bending, when cold, without showing crack or flaw, as follows:—

For iron, $\frac{3}{4}$-inch thick through an angle of 120 degrees.
„ $\frac{5}{8}$-inch „ „ 130 „
„ $\frac{1}{2}$-inch „ „ 140 „
For steel, all thicknesses, through an angle of 180 degrees.

In all cases the inside radius of the bend shall be not greater than $1\frac{1}{2}$ times the thickness of the test piece.

Laminated Springs—B.S.S. 6A.

Same as specification B.S.S. 6, except that spring plates shall be manufactured from steel made from selected material by the acid or basic open-hearth or the acid Bessemer process. In the event of the basic open-hearth process being employed, the maximum percentage of sulphur and phosphorus must not exceed ·05 per cent.

Laminated Springs—B.S.S. 6B.

The spring plates and bars shall be manufactured from the highest quality of steel made from the best selected material by the acid open-hearth process, and must not show on analysis more than ·8 per cent. nor less than ·5 per cent of carbon, nor more than ·05 per cent. of sulphur or of phosphorus. The steel plates or bars to be used for top plates, which have to be welded at the eye, must not contain more than ·7 per cent. nor less than ·45 per cent. of carbon.

As a test-pieces of steel 30 ins. long shall be cambered to a radius of eighty times their thickness, as shown below, hardened and tempered, and after being pressed straight once, and the camber carefully noted, must stand being pressed straight again six times in quick succession without any permanent set.

	Ins.	Ins.	Ins.	Ins.	Ins.
Thickness of plate . . .	$\frac{3}{4}$	$\frac{7}{16}$	$\frac{1}{2}$	$\frac{9}{16}$	$\frac{5}{8}$
Required camber . . .	$3\frac{3}{4}$	$3\frac{1}{8}$	$2\frac{3}{4}$	$2\frac{1}{2}$	$2\frac{1}{4}$
Minimum camber after first blow and the next six consecutive blows	$3\frac{3}{8}$	$2\frac{7}{8}$	$2\frac{1}{2}$	$2\frac{1}{4}$	2

Laminated Springs—B.S.S. 6C.

Material for spring plates and bars same as B.S.S. 6A. Tests same as B.S.S. 6B.

Volute and Helical Springs—B.S.S. 7.

The springs shall be manufactured from the highest quality of steel made from the best selected material by the acid open-hearth process. The steel must not show more than 1·3 per cent. nor less than ·8 per cent. of carbon, and not more than ·05 per cent. of sulphur or of phosphorus.

Each spring shall be tested by being driven home once by a quick-acting scrag, the height being carefully noted after release. The spring must then stand being driven home again five times in quick succession without showing any permanent set. Up to 5 per cent. of the springs shall also be tested under varying loads to determine the range and deflection per ton.

All springs shall be hardened in oil and tempered in a bath of molten lead.

Volute and Helical Springs—B.S.S. 7a.

The springs shall be manufactured from the highest quality of steel made from the best selected material by the acid open-hearth or the acid Bessemer process, and must not contain more than 1·3 per cent. nor less than ·8 per cent. of carbon.

Test same as B.S.S. 7.

Steel Forgings for Locomotives—B.S.S. 8.

The forgings shall be manufactured from steel made by the acid or basic open-hearth process.

The tensile breaking strength and minimum elongation on Standard Test Piece C or D to be as follows :—

Class.	Description of Forging.	Process of Manufacture.	Percentage of Sulphur or of Phosphorus.	Tensile Breaking Strength in tons per square inch.	Minimum Elongation per cent.
A	Special forgings which will be case-hardened	Acid or basic open-hearth	·05	Up to 27 tons	25
B	Ordinary forgings	Do.	·06	25 to 32 with	27
C	Special forgings without wearing surfaces	Acid open-hearth	·05	32 to 38 with	20 25
D	Special forgings with wearing surfaces	Do.	·05	40 to 45 with	20 20
E	Boiler forgings	Do.	·05	26 to 32 with	15 28 to 22

The sums of the tensile breaking strengths and corresponding elongations must be not less than 52 for Classes A and B, 57 for Class C, 60 for Class D, and not less than 54 for Class E. In the case of Classes C and D the yield point must be not less than 50 per cent. of the ultimate tensile strength.

A test piece, 9 inches long and 1¼ inch square, or as near this size as the forging or forgings selected will permit, with $\frac{1}{16}$ inch radius at the edges, machined cold, must, without any reheating, withstand being bent cold by direct pressure from a tool 1½ ins. wide in the case of Classes A, B, and E, 1¾ ins. wide in the case of Class C, and 2½ ins. wide in the case of Class D, the ends having a radius respectively of ¾ in., $\frac{7}{8}$ in., and 1¼ ins., until the sides of the test pieces are parallel. The ends of the test pieces of all classes of forgings, except Class D, shall then be brought together without fracture by direct pressure.

All forgings in Classes C and D shall be either normalised or oil-treated.

Steel Blooms for Locomotive Forgings—B.S.S. 9.

Specification and tests for Classes A, B, C, D, and E same as for B.S.S. 8.

Test pieces cut from blooms may be normalised or oil-treated.

Steel Castings—B.S.S. 10.

The castings shall be manufactured from steel produced by an approved process, and must not show on analysis more than ·07 per cent. of sulphur or of phosphorus.

All castings shall be thoroughly annealed by heating to a temperature not less than the normalising temperature and allowing to cool slowly from the maximum temperature in a practically uniform manner.

The minimum tensile breaking strength and elongation on Standard Test Piece C or D to be as follows :—

Description of Casting.	Minimum Tensile Breaking Strength per square inch.	Minimum Elongation per cent.
Castings with wearing surfaces	35 tons	10
Other General Castings and Wheel Centres	26 tons	15

In the case of castings other than those with wearing surfaces, a test piece 9 ins. long, turned to 1 in. diameter, must withstand being bent cold through an angle of 90 degrees round a bar 2½ ins. diameter without fracture.

When wheel centres are tested to destruction, the test shall be made by dropping the wheel centre on to a block of metal of not less than 5 tons weight, supported upon a rigid concrete or other solid foundation. The wheel centre shall be raised and allowed to fall freely in a running position through distances of 5 ft. and 10 ft. on the end of a spoke (where such exists), and then

turned through 90 degrees and again raised and allowed to fall freely in a running position through distances of 5 ft. and 10 ft. on the end of a spoke (where such exists). Any sign of failure under this test will render the wheel centres liable to rejection. The test shall then be continued, the fall being increased 5 ft. each time until fracture results or the wheel centre is doubled up.

Copper Plates for Locomotive Fire-boxes—B.S.S. 11.

(Report No. 24—1911.)

The plates shall be of one of two classes, to meet the largely varying chemical constituents of coal, and differing conditions of use, and must comply with the requirements specified below :—

Class A.—The plates must contain not less than 99 per cent. of copper, and ·35 per cent. to ·55 per cent. must consist of arsenic.

Class B.—The plates must contain not less than 99·25 per cent. of copper, and ·25 per cent. to ·45 per cent. must consist of arsenic.

Tensile breaking strength to be not less than 14 tons per square inch, with an elongation of not less than 35 per cent. on Standard Test Piece A.

Pieces of the plate shall be tested both cold and at a red heat by being doubled over on themselves—that is, bent through an angle of 180 degrees, without showing either crack or flaw on the outside of the bend.

Copper Rods for Locomotive Stay Bolts, Rivets, etc.—B.S.S. 12.

The rods must contain not less than 99·25 per cent. of copper, and ·15 per cent. to ·35 per cent. must consist of arsenic.

The tensile strength must be not less than 14 tons per square inch, with an elongation of not less than 40 per cent. on the standard test-piece having a gauge length of not less than eight times the diameter. When a very small test-piece is required, the standard test-piece having a gauge length of 3 ins., the elongation must be not less than 45 per cent.

A piece of rod 1 in. long shall be placed on end and hammered or crushed down to a thickness of $\frac{3}{8}$ in., without showing either crack or flaw on the circumference of the resulting disc.

Copper Tubes for Locomotive Boilers.—B.S.S. 13.

The tubes must contain not less than 99 per cent. of copper, and ·35 per cent. to ·55 per cent. must consist of arsenic.

The tubes must stand bulging, without showing either crack or flaw, until the diameter of the bulged end measures not less than 25 per cent. greater than the original diameter of the tube.

The tubes must stand flanging, without showing either crack or flaw, until the diameter of the flange measures not less than 40 per cent. greater than the original diameter of the tube.

The tubes must be capable of standing the following flattening and doubling over test, both cold and at a red heat, without showing either crack or flaw. A piece of the tube shall be flattened down until the interior surfaces of the tube meet, and then be doubled over on itself, that is, bent through an angle of 180 degrees, the bend being at right angles to the direction of the length of the tube.

All copper boiler tubes shall be tested by an internal hydraulic pressure of at least 750 lbs. per square inch.

Brass Tubes for Locomotive Boilers—B.S.S. 14.

Brass for locomotive boiler tubes may be of either 70/30 alloy or 2/1 alloy.

The tubes must consist of an alloy of copper and zinc, and must contain :—

70/30 Alloy.—Not less than 70 per cent. of metallic copper and not more than a total of ·75 per cent. of materials other than copper and zinc.

2/1 Alloy.—Not less than 66·7 per cent. of metallic copper and not more than a total of ·75 per cent. of materials other than copper and zinc.

The tubes shall be carefully annealed at both ends.

The tubes must stand bulging, without showing either crack or flaw, until the diameter of the bulged end measures not less than 25 per cent. greater than the original diameter of the tube.

The tubes must stand flanging, without showing either crack or flaw, until the diameter of the flange measures not less than 25 per cent. greater than the original diameter of the tube.

Flattening and doubling-over test the same as for copper boiler tubes.

Tubes to be tested by an internal hydraulic pressure of at least 750 lbs. per square inch.

Weldless Steel Tubes for Locomotive Boilers.

(Report No. 53—1913.)

1. The tubes shall be cold-drawn and weldless and shall be manufactured from steel of the best quality by the open-hearth process. They must not show, on analysis, more than 0·03 per cent. of sulphur or of phosphorus.

2. The tubes must be perfectly sound, well finished, clean, and free from surface defects and rust, and the ends must be faced clean and square. They must be of the dimensions specified, of uniform thickness, and, unless otherwise specified, of uniform diameter throughout.

3. The tubes shall be carefully annealed throughout their length after the operation of drawing.

6. The tubes or strips cut from the tubes shall, without further annealing, show a tensile strength of not more than 24 tons per sq. in., with an elongation of not less than 28 per cent. in 8 ins.

7. The tubes must, when cold, stand bulging without showing either crack or flaw until the diameter of the bulged end measures not less than 15 per cent. for tubes under 11 s.w.g. in thickness, and not less than 12½ per cent. for tubes 11 s.w.g. to 8 s.w.g. in thickness, greater than the original diameter of the tube (fig. 19).

8. A piece of tube, 2 ins. long, shall be placed on end and must, when cold, stand hammering down, until it is reduced to 1½ in. high, without showing either crack or flaw.

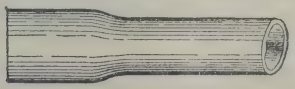

Fig. 19.

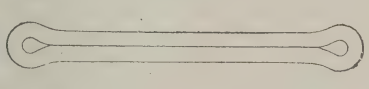

Fig. 20.

9. The tubes must, when cold, stand flattening without showing crack or flaw until the interior surfaces of the tubes meet, or, when the tubes are over 11 s.w.g. in thickness, until the interior surfaces are brought to a distance apart equal to the thickness of the wall of the tube (fig. 20).

10. Every tube shall be tested by an internal hydraulic pressure of at least 1,000 lbs. per sq. in.

Seamless Copper Tubes for Locomotive Feed Pipes, etc.—B.S.S. 15.

(Report No. 24—1911.)

The tubes must contain not less than 99·25 per cent. of copper, and ·25 per cent. to ·45 per cent. must consist of arsenic.

The tubes must stand drifting, without showing either crack or flaw, until the diameter of the drifted end measures at least 25 per cent. greater than the original diameter of the tube.

Flattening and doubling-over test the same as for copper boiler tubes.

Hydraulic pressure test to be according to requirements.

Steel Plates, Angles, etc., and Rivets for Locomotive Boilers—B.S.S. 16.

(Report No. 24—1921.)

The plates, sections and bars shall be manufactured from steel made from selected material by the acid or basic open-hearth processes, as may be specified. The steel must not show on analysis more than ·05 per cent. of sulphur or of phosphorus.

When plates are required for flanging purposes it shall be so stated at the time of inquiry.

Test pieces to be cut crosswise from rolled material in case of plates, and lengthwise in case of sectional material. When material is annealed or otherwise treated before dispatch, the test pieces shall be similarly and simultaneously treated with the material before testing. Any straightening of test pieces shall be done cold.

For plates, angles, etc., a Standard Test Piece A, and for round bars (other than rivet bars a Standard Test Piece B, must show a tensile breaking strength of 26 to 30 tons per sq. in., with an elongation of not less than 22 per cent. When bars are above 1 in. in diameter and are tested full size as rolled, or have been turned down and the resulting test piece is above 1 in. in diameter, Standard Test Piece F may be used, in which case the elongation shall be not less than 27 per cent.

For rivet bars Standard Test Piece B must show a tensile breaking strength of 24 to 28 tons per sq. in., with an elongation of not less than 27 per cent. If tested on Standard Test Piece F the elongation shall be not less than 32 per cent. The bars may be tested the full size as rolled.

For both cold and temper bends the test piece must withstand, without fracture, being doubled over until the internal radius is not greater than the thickness of the test piece, and the sides are parallel.

Bend tests may be made either by pressure or by blows. For rivet bars temper bend tests only are required.

In all cold or temper bend tests the sheared edges may be removed by milling, planing, grinding, or other method. The cold bend test pieces shall not be annealed, unless the material from which they are cut is similarly annealed, in which case the test pieces shall be similarly and simultaneously treated with the material before testing.

For temper tests the test pieces shall be heated to blood red and quenched in water at a temperature not exceeding 80 deg. Fahr.

Tests for Manufactured Rivets.—The rivet shanks shall be bent cold, and hammered until the two parts of the shank touch, without fracture, on the outside of the bend. The rivet heads shall be flattened without cracking at the edges until the diameter of the head is 2½ times the diameter of the shank.

Steel Plates, Angles, etc., and Rivets for Locomotive Frames—B.S.S. 17.

(Report No. 24—1911.)

The plates, sections and bars shall be manufactured from steel made from selected material by the acid or basic open-hearth process. If the specification is *with analysis*, the steel must not show more than ·06 per cent. of sulphur or of phosphorus.

Plates must show a tensile breaking strength of 28 to 32 tons per square inch, with an elongation on Standard Test Piece A of not less than 20 per cent. for plates of ·375 in. in thickness and upwards, and 16 per cent. for plates below ·375 in. in thickness.

Sectional material must show a tensile breaking strength of 28 to 32 tons per square inch, with an elongation of not less than 20 per cent. on Standard Test Piece A or B, or 24 per cent. with Standard Test Piece F. For material under ·312 in. thick bend tests only are required.

Rivet bars must show a tensile breaking strength of 24 to 28 tons per square inch, with an elongation of not less than 27 per cent. on Standard Test Piece B, or 32 per cent. with Standard Test Piece F. Bars may be tested full size as rolled.

Cold and temper bend tests and tests for manufactured rivets same as B.S.S. 16.

Steel Plates, Angles, etc., and Rivets for Locomotive Frames—B.S.S. 17a

Same as B.S.S. 17, but without analysis.

Steel Plates, Angles, etc., and Rivets for Carriage and Waggon Underframes—B.S.S. 18, B.S.S. 18a.

Specifications same as for locomotive frames, B.S.S. 17, B.S.S. 17a.

Wrought Iron.

(Report No. 51, 1913.)

Specifications are given for wrought iron, best Yorkshire and Grades A, B, and C. The tensile tests, etc., vary with the sizes of the different sections rolled.

Other Materials used in Locomotive Construction.

Iron Castings.—The tensile test is the most trustworthy; 7 tons per sq. in. is the usual specification; 8 and 9 tons may be demanded in reason and expected. General foundry iron up to 11½ and 12½ tons per sq. in. and cylinder iron up to 13½ and 14 tons per sq. in. are not unknown, each having good fractures, and being good workable foundry metal. The usual commercial test is generally made transversely upon bars 3 ft. long, 2 ins. deep, and 1 in. thick, without being machined, 25 to 32 cwts. being the specified central breaking load. The test bars should be cast by means of an attachment to the casting, and the specified ultimate loads should not vary more than 1 per cent.

Bronze, Brass, White Metals, and other Alloys.—These compositions can be produced in almost infinite variety. Generally they should be homogeneous, that is, liquation must be prevented as well as oxidation. Examples of the composition per cent. are given in the following table :—

TABLE SHOWING COMPOSITION OF ALLOYS FOR PARTS OF LOCOMOTIVE ENGINES.

Description.	Copper. Cu.	Tin. Sn.	Zinc. Z.	Lead. Pb.	Phosphorus. P.	Iron. Fe.	Silicon. Si.
Bronze, old copper tin alloy	87·5	12·5	..	..	..	..	..
„ a standard American bearing	80·0	10·0	..	9·5	0·5	..	..
„ English, generally	80·0	18·0	2	0·5	..	..	..
	88·0	10·0	2	0·5	..	..	..
„ „ slide valves	82·5	14·5	..	..	0·36	2·0	0·04
„ „ „ „	85·0	11·6	3·9	..	0·16	..	..
„ „ „ „	83·5	6·0	..	10	1·5 to 0·5	..	..
Brass, English, generally	70·0	..	30·0	0·5	..	..	..

For white or antifriction metals lead now forms the base (originally tin), with a varying quantity of antimony as a hardener. Ferro, silicon, manganese, and aluminium bronzes are produced to meet specific requirements.

See also Section XXXVII (Metallurgy).

Contract Specification.

The *Contract Specification* should also provide for delivery and payment after running a guaranteed mileage (about 3,000 to 5,000). That all parts shall be constructed exactly to the drawings supplied, and no deviation made whatever without consulting those responsible for letting the contract, and that lack of information shall be no excuse for discrepancies in material or construction. The price quoted must be inclusive, and no responsibility shall devolve upon the purchaser for royalties and patent rights. The quotation should also include drawings (2 complete sets), photographs (12), lists of details, weights, etc., to be furnished with the (3rd of 5th) engine.

It should also stipulate that the workmanship should be accurate and well finished.

Use of Materials made to British Standard Specifications.

(Report No. 24—1911 & 1921.)

No. 1.—Crank axles.

Nos. 2 *and* 2A.—Straight axles, locomotive and tender.

Nos. 3 *and* 3A.—Carriage and waggon axles.

No. 4.—Tyres for locomotive and tender. Class C is the most commonly specified.

Nos. 5 *and* 5A.—Carriage and waggon tyres. Class C for carriages and Class B for waggons are the most commonly specified.

Nos. 6 *and* 6A.—Laminated springs, purchased complete.

Nos. 6B *and* 6C.—Plates and bars for manufacturing laminated springs, spring wearing plates, flat springs.

Nos. 7 *and* 7A.—Manufactured volute and helical springs.

No. 8.—Steel forgings of Classes A to E (as below).

No. 9.—Steel blooms for making forgings. *Class A* is used for motion work and pins and other parts requiring to be case-hardened ; spring hangers and links, brake work, draw bar, and safety links and pins, coupling screw and shackle, regulator rod, fire hole ring, foundation ring, and other parts requiring a weld. *Class B* for ordinary forgings, valve spindles, motion work not requiring case-hardening, reversing shaft and rod, reversing screw, buffer heads, regulator handle, roof slings, safety valve, and other seatings, wash-out doors and bridges, etc. *Class C*., connecting and coupling rods, crossheads, keys and cotters. *Class D*, piston rods, slide bar, crosshead cotter. *Class E*, boiler forgings.

No. 10.—Steel castings. Wheel centres form one class ; castings with wearing surfaces another, and this includes axle boxes and guides, bogie centres, bogie slide, brake shaft brackets, spring brackets, buffer plungers and guides. General castings without wearing surfaces include motion plate or slide bar brackets, smoke-box saddle, etc.

No. 11.—Copper fire-box plates.

No. 12.—Copper stays and studs.

No. 13.—Copper boiler tubes.

No. 14.—Brass boiler tubes.

No. 15.—Copper pipes for feed water and steam.

No. 16.—Boiler barrel and fire-box shell plates, front tube plate, rivets, stays, nuts, angles rods, etc., for boiler work. Expansion brackets, roof stays, palm stays.

Nos. 17 *and* 17A.—Locomotive and tender frame plates and cross stays, angles, bolts, rivets, plating, ash pan and doors, fire door, smoke-box and door, cab, tender tank plates, etc.

Nos. 18 *and* 18A.—Steel plates, angles, and other sectional material for carriage and waggon underframes.

Report No. 53 (1913).—Weldless steel tubes for boilers.

Liquid Fuel.

On the Great Eastern Railway, express engines can be fired with coal only on a consumption of about 50 lbs. per mile, or with coal and liquid fuel combined, on a consumption of 10 lbs. of coal and 30 lbs. oil fuel, including lighting up in each case.

The suitable oil fuels consist of petroleum residue, or Astatki, having a specific gravity of ·905, flash point 214° F.; distillates from coal gas tar with a specific gravity of 1·11, flash point 196° F.; coal gas tar with a specific gravity of 1·23, flash point 200° F.; or oil gas tar (refined) with a specific gravity of 1·05, flash point ·30° F.

The theoretical efficiency of oil fuel can be more nearly approached in practical working than that of coal, and with petroleum residue (the best oil fuel), 66·6 per cent. of its heat can be transferred into steam, whereas with steam coal 55·5 per cent. is about the average.

Engine No. 1862, a four-coupled bogie express, with a train weighing about 250 tons, exclusive of engine, ran from Liverpool Street to Cambridge on an expenditure of 120 gallons of oil fuel

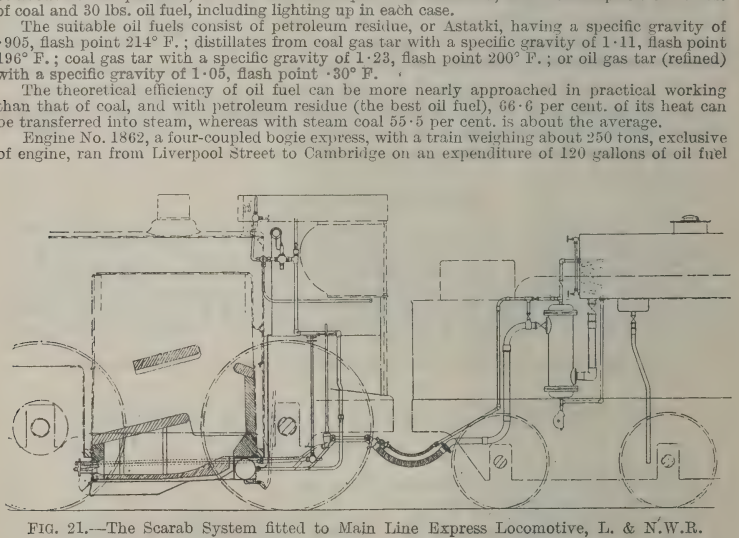

FIG. 21.—The Scarab System fitted to Main Line Express Locomotive, L. & N.W.R.

—oil gas tar—and a layer of coal and broken firebrick on the firebars. Steam was easily kept up during the trip, and no smoke was emitted from the chimney, thus showing that complete combustion of the fuel was effected (Holden's system).

On the L. & N.W.R. an engine of the 'Precursor' 4–4–0 class (non-superheater) has recently been fitted for burning oil (fig. 21), of which 1,000 gals. is carried in a special tank mounted on the tender and filled by means of a semi-rotary hand-pump fixed at the rear end of the tank. The burners are made by the Scarab Oil Burning Co., and are of the gravity-feed type, the atomising agent being steam, which is supplied at a pressure of from 10 to 15 lbs. per sq. in. through a reducing valve. A receiver is interposed between reducing valve and burners to steady the supply. The burners are below the front of the firebox and supported by a casing which also supports the fire-brick floor of the firebox. Air-ducts are arranged underneath the floor so that the air supply is preheated. Three arches are provided, one immediately above the burners springing from near the foundation ring, another arranged as in a coal-burning engine but stopping off about 16 ins. from the tube plate, and a third under the firehole door. Brickwork is carried up from the floor as far as the baffle arch. This construction, by lowering the floor, increases the capacity of the box, which makes for improved combustion. The flooring just in front of the burners is perforated, allowing of a supply of air from the duct to be delivered under the point where the oil breaks into flame. Three burners, one centre and two side, are

fitted, but it is found that the best results are obtained from the centre burner alone, and it is capable of generating enough steam to take trains up to the rated capacity of the locomotive. The raising of steam is accomplished by coupling up to another engine by means of a flexible pipe. In this way steam is obtained for atomising the oil, and for the blower, which is kept in action while steam is raised. A Royle heater is fitted for heating the oil supply in cold weather, so that it flows readily. Arrangement is also made for blowing out the oil supply pipes with steam in order to keep them clean. On one trip the oil consumption recorded was 32 lbs. per

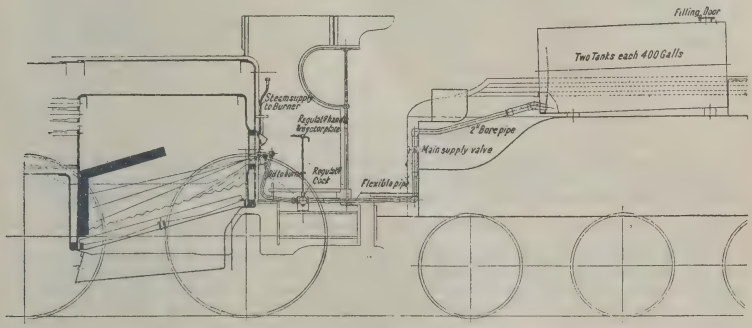

FIG. 22.—Midland Railway Oil-firing Arrangement.

mile, or 10·88 lbs. per 100 ton-miles with a train of 294 tons; and 24⅛ lbs. per mile, or 9·25 lbs. per 100 ton-miles with a train of 264 tons. The average consumption of coal by the same engine is about 70 lbs. per mile.

The Midland Railway burns oil in conjunction with a certain amount of coal; the burner is inserted through the fire-hole door, no alteration being made to the fire-box except by bricking up the portion of the tube plate under the brick arch (fig. 22). The oil issues from the top

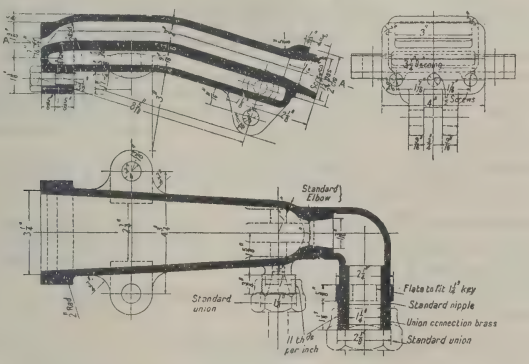

FIG. 23.—Oil Fuel Burner, Midland Railway.

portion of the burner in a thin stream or ribbon, and is atomised by coming in contact with a flat jet of steam which issues immediately under it from an orifice somewhat wider than that through which the oil flows. The details of the burner are shown in fig. 23.

The burner is inserted in the fire-hole, and is fed from two tanks placed on the tender, each of which holds from 400 to 500 gals. of oil. The flame is directed under the brick arch; the top portion of the fire-hole is closed by a special door which can be opened if it is necessary to use coal.

The fire-bars are covered with a layer of broken fire-brick, and if it is at any time necessary to use a little coal, it is put at the back of the fire-box. The fire can be started with wood, and as soon as the steam pressure reaches about 40 lbs. the burner can be used. In many cases no coal whatever is burnt for long periods, the engine steaming freely and the fire requiring very little attention. The best steaming results are, of course, obtained when there is a slight amount of smoke given off at the chimney. The locomotives fitted with this arrangement are able to deal easily with their accustomed loads. The advantage of the system is the ease with which it can be fitted up, and the simplicity in handling.

The company has one engine in which a similar burner is fitted in front of the ashpan, the fire-box being suitably bricked in on the sides and ends. (*The Engineer.*)

See also Section XXXI, FUELS, page 1767.

Lubricating Oil Consumption.

The oil consumption of different railways varies considerably, but under favourable conditions 1 lb. of cylinder oil and 4 lbs. of engine oil are required per 100 miles. Superheater engines use rather more cylinder oil than non-superheater, and the quality of the oil is more expensive.

The oil consumption of the 4-6-0 Great Western Engines averages 5 lbs. per 100 miles.

Sight feed lubricators on the hydrostatic principle, delivering oil to the steam pipes, are used on both superheater and non-superheater engines. It is more usual on superheater engines to employ a mechanical force feed lubricator driven by an attachment to some part of the engine motion. In this case oil is delivered direct to the piston valve heads, and the middle of each cylinder bore.

The practice of feeding oil to the crowns of axle boxes by mechanical lubricators is also extending, more particularly in the case of heavy eight wheels coupled mineral engines.

FOR LUBRICATION AND LUBRICATORS, see page 909.

Fuel Consumption.

The consumption of fuel varies to a considerable extent, but may be taken for English express engines from about 30 to 40 lbs. per train mile. Hard firing is not economical; the carbonic oxide escapes unburnt. Approximate perfection is approached when about 50 or 60 lbs. of fuel is consumed per hour per sq. ft. of grate area.

The average coal consumption of the non-superheated 'Precursor' type locomotives engaged in working the principal express passenger services of the London and North Western Railway is 56 lbs. per mile. The superheater locomotives of the same general pattern consume only about 38 lbs. per mile, while for the run between London and Holyhead their consumption has been as low as 34½ lbs. per mile as a monthly average.

E. A. Johnston states that the average rate of combustion in British express engines on heavy service is about 100 lbs. per sq. ft. of grate area per hour, and about 50 lbs. of coal per mile; the maximum rate may reach 160 lbs. per sq. ft. of grate area per hour.

The evaporative power of locomotive boilers amounts to from 7 to 10 lbs. of water per pound of coal consumed. Longridge states that no rule can be fixed as to the best relative proportions of heating surface between grate area, fire-box, and tubes. It is an axiom that the capacity of a locomotive depends entirely upon its fire-box.

The consumption of fuel in a locomotive engine at rest is about one-fifth of that consumed when the engine is in motion.

American locomotives running at 43 miles per hour, and drawing a total of 250 tons, burn 50 lbs. of coal per mile. Their weight averages 100,000 lbs.

Water Consumption.

With a piston speed of 900 ft. per minute and a boiler pressure of 175 lbs. per sq. in., locomotives using saturated steam require about 24 lbs. per i.h.p. hour. The evaporation is approximately 8 lbs. of water per pound of coal, or 9½ lbs. from and at 212°F. The coal consumption is therefore 3 lbs. per i.h.p. hour. Locomotives using superheated steam require 25 per cent. less, or about 18 lbs. of steam per i.h.p. hour. The coal per i.h.p. is 12½ per cent. less, or roughly 2¼ lbs. per i.h.p. hour, the evaporation being 7 lbs. of water per pound of coal.

Examination of Locomotives at Running Sheds.

A failure on the road is a serious matter, and the best way of reducing breakdowns to a minimum is by periodical examinations. The following is a list of the usual examinations of the G.N.Rly.:—

Slide valves:—	
Piston valves	2 months
Richardson's	2 ,,
'D' valves, $\frac{7}{8}$ in. thickness	4 ,,
'D' ,, $\frac{3}{4}$ and $\frac{11}{16}$ in. ,,	3 ,,
'D' ,, $\frac{5}{8}$ and $\frac{9}{16}$ ins. ,,	2 ,,
'D' ,, $\frac{1}{2}$	1 month
Pistons	3 months
Tender tanks	1 month
Drip valves	1 ,,
Safety valves	6 weeks
Ball valves in water gauge frames (dependent upon quality of water in district.)	2 months
Lead plugs	1 month
Large ends	3 months
Small ends	6 months
Vacuum regulating valves	1 ,,
Water scoops	1 ,,
Fire-boxes	1 week
Axle-box pads	3 months
Injectors	1 month
Main steam pipes on superheated engines	1 ,,
Tender wheels gauged	1 ,,
Leading wheels of 2–4–0 type gauged	1 ,,
Engine and tender tyres gauged	1 ,,
Mechanical lubricators to slide valves and pistons	2 ,,
Mechanical lubricators to axle-boxes	1 ,,

Cracked frames, flaws in connecting and coupling rods, or any part of motion, loose tyres, etc., should also be watched for. (*G. A. Musgrave, 'Proceedings, Inst. Loco. Engrs.'*)

Engine and Tender Tools and Equipment.

Carried in Tool Boxes.

Flat chisel
Pin punches (large and small).
Chipping hammer.
Wrench for Union nuts.
Complete set of spanners
Adjustable wrench.
Tommy bar.
Large can for engine oil (6 to 8 quarts).
Large can for cylinder oil (6 to 8 quarts).
Small can for paraffin (about 1 quart).
Spring valve oil feeder, long spout.
Spring valve oil feeder, short spout.
Flare lamp.
Case of fog signals.
Red flag.
Hand sweeping brush.
Packing drawer, Tallow pot. } (if required).
Spare glasses for water gauge.
Spare glasses for sight feed lubricator (if fitted).
Spare packing rings for glasses.
Copper wire for trimmings.
Worsted for trimmings.
Spare cotter pins.
Spare nuts.

Carried on Tender.

Fire rake, Pricker, Dart, Tube scraper, Clinker shovel. } (length to suit firebox).
Slice (to suit depth of firebox at back).
Coal hammer.
Coal pick.
Pinch bar.
Bucket.
Fireman's shovel.
Screw-lifting and traversing jack (if specified).

Other Equipment.

Full set of head and tail lamps.
Full set of head boards or discs (when used).
Water gauge lamp.
Sight feed lubricator lamp (if required).

Special Equipment at Shed for Class of Engine.

Spanner for brake screw adjusting nuts.
Box spanner for fusible plugs.
Ashpan rake.

Tenders.

The water capacity of tenders on British railways varies considerably. On the London and North Western Railway many tenders are under 3,000 galls. and the Great Western Railway uses 3,500 galls. for the largest engines, but these railways possess numerous water troughs, so that light six-wheeled tenders suffice. The London and South Western and the Caledonian Railways have large bogie tenders of some 5,000 galls. capacity.

The coal capacity does not vary so much, and lies between five and seven tons, depending on the size of the engine.

The connection between engine and tender consists of a simple eye-ended bar with one or both holes elongated to allow for the buffing which is taken up at the centre on a massive helical spring through which the bar passes. Safety links or loops are provided on either side but only come into operation in the event of the bar breaking.

Several railways prefer side buffers as they help to damp out oscillations of the engine by the friction of the rubbing surfaces. The central arrangement is better for sharp curves.

Water Troughs.

Effective length s from 440 to 560 yards. Theoretically a quantity of about 1,000 gallons can be picked up, the mouth of the scoop being at rail level and 1½ ins. below water level. In practice considerably more is obtained owing to the heaping up of the water in front of scoop, the maximum being obtained at 45 miles per hour with some 1,700 galls. At higher speeds there is a considerable loss by spray. The lowest speed at which water can be picked up is 15 miles per hour.

When running at 60 miles an hour over a water trough ¼ mile long, a locomotive tender will pick up about 1,000 gallons or 10,000 lbs. of water.

Brakes.

In addition to hand brakes the majority of engines and tenders are fitted with power brakes usually the standard Westinghouse or Automatic Vacuum apparatus (page 631). The larger railways manufacture their own vacuum brake fittings. Goods engines not fitted with a continuous brake have a simple steam brake. Many engines are fitted with a steam brake working automatically with the vacuum by means of a valve of simple construction which can either be controlled by the vacuum in the train pipe or by hand. This is found to be a convenience, and the brake cylinders being of small diameter occupy but little space under the engine. The arrangement is extensively used on the Midland and other railways and gives very satisfactory results.

Instead of a small ejector for maintaining the vacuum in the train pipe, several railways employ a vacuum pump about 5 ins. bore directly driven from one of the crossheads of the engine. As the pump is capable of creating a high vacuum a relief valve is provided to limit the vacuity. On the Great Western Railway this is set for 25 ins., resulting in a running vacuum of 26 ins. of mercury. The London and North Western and one or two other railways set the valve for the standard 20-inch vacuum, which results in 22 inches being maintained when running. Less trouble from pumps running hot is experienced with the higher vacuum, and the size of brake cylinders or leverage is reduced a little on account of the greater available atmospheric pressure, but no practical difficulties arise in the interchange of rolling stock with other railways.

The percentage of brake power, that is pressure on brake blocks in relation to load on wheels, should not exceed 75 per cent. for coupled wheels and 100 per cent. of weight when empty for tenders. If bogie wheels of engine are braked the percentage should not exceed 50 in order to minimise any chance of skidding.

To avoid frequent taking up of blocks brake leverage should not be too great. With steam and air brakes leverage is about 7 to 1; vacuum brakes are sometimes as much as 14 to 1 on account of difficulty of finding room for large cylinders. With this ratio a 7-inch piston travel allows ¼ inch clearance for blocks and ¼ inch wear.

Steam Rail Motor Cars.

A large number of rail motor cars were built between the years 1904 and 1909. There are two principal types, one having a steam bogie at one end on which a vertical boiler is mounted. The Great Western Railway have approximately 100 of these cars, half of which are 70 feet long

over headstocks, the rest being nearly all 59 ft. 6 ins. in length. The cylinders are 12 ins. by 16 ins., the wheels 4 ft. diameter, water capacity of tanks 450 galls. The boiler is vertical, 4 ft. 6 ins. diameter with cone top, and has 458 tubes 1⅛ in. diameter, total heating surface 659 sq. ft. and grate area 11½ sq. ft. The pressure is 160 lbs. per sq. in. and the tractive effort 6,912 lbs. The 70 ft. cars seat 61 passengers and the weight on motor bogie is 26·9 tons, and on the trailing bogie 16·25 tons. Walschaert valve gear is fitted. The other type of rail motor car consists of a miniature tank locomotive on which one end of the car body rests, the trailing end being carried as usual on a standard carriage bogie. The dimensions and weights are very much the same as for the first type.

Very few cars have been built during the last ten years. The tendency is to use up obsolete locomotives and carriages by suitably converting them for motor services. A small tank engine is attached to one or more trailer cars to form a unit which can be driven from either end. When pushing the car, the locomotive is controlled by the driver from the opposite end of the train by means of levers and rods with universal joints connected to the regulator. A brake valve and whistle cord are provided and an electric bell signal enables the driver to communicate with the fireman on the footplate.

ROLLING STOCK.

(Revised by H. Holcroft, M.I.Loco.E.)

GREAT WESTERN RAILWAY.

Corridor Bogie Carriages.

Length.	Type of Vehicle.	Weight.	Length.	Type of Vehicle.	Weight.
Ft.		Tons Cwt.	Ft.		Tons Cwt.

LONDON AND SOUTH WESTERN RAILWAY.

Carriages.

Principal express trains are formed of corridor stock consisting of the following vehicles :—

	Length.	Seats. 1st.	3rd.
Dining-car (with kitchen)	56 feet	11	17
Bi-composites	54 ,,	12	24
	54 ,,	16	18
Bi-composite (with guard's brake)	56 ,,	8	28
Thirds	56 ,,		64
Third brakes	56 ,,		32

The principal main line trains are formed of sets of lavatory coaches, each coach 56 ft. long, and each set of 4 coaches having 26 first and 160 third-class seats.

The principal suburban services are worked by sets of 8 coaches, divisible in the centre; 4 coaches only being used during that part of the day when the traffic is light. Each set of 4 coaches has 2 third brakes, 51 ft. long, 1 composite 51 ft. long, and 1 composite 49 ft. long, the total seating accommodation being 42 first and 218 third-class.

The branch line services are performed by two coach bogie sets, accommodating 10 first and 84 third-class passengers.

Trains for Bournemouth Service.—The coaches are of the corridor type. Each train has seating accommodation for 42 first and 154 third-class passengers, and consists of five coaches, as follows :—

Brake third . . 4 compartments, one lavatory and one baggage compartment.

Third	8	compartments, two lavatories.
Pantry third	7	,, one lavatory, one pantry.
First	7	,, two lavatories.
Brake third	4	,, one lavatory, one baggage compartment.

PRINCIPAL DIMENSIONS.

	Ft.	Ins.		Ft.	Ins.

* Shelves.

Waggons.

The coal trains convey 41 to 60 loaded waggons, according to the gradient of the road, the carrying capacity of each being 10 tons; other coal waggons have a carrying capacity of 20, 30 and 40 tons. Tare of waggons, 300 tons. The empty trains comprise up to 90 waggons. Covered fish trucks are 45 feet long. For carrying special articles, such as armour plates and guns, waggons are made to carry castings up to 80 tons, and guns up to 100 tons and over, on the cantilever system.

NORTH EASTERN RAILWAY.

Carriages.

Standard Passenger Coaches—52 ft. long over headstocks, by 8 ft. 6 ins. wide over waist moulding, 9 ft. wide over all projections; they contain 8 compartments of third class, each seating 10 passengers; tare weight 24 tons including Westinghouse brake and steam heating.

Ordinary Standard Passenger Train—5 vehicles (average) 52 ft. long, comprising one of third class as above, one semi-corridor lavatory composite with access to lavatory from two first and two third class compartments, 29 seats for first class and 24 for third, one luggage composite with three first and four third class compartments, seating 24 first and 40 third class passengers, and luggage locker 4 ft. 6 ins. wide, also two brake thirds. Total seating capacity, 53 first and 204 third; weight of train, 120 tons.

Corridor Vestibuled Dining Train—6 vehicles 52 ft. long by 9 ft. wide over waist moulding, and one dining car with kitchen 65 ft. 6 ins. long by 9 ft. wide, British Standard vestibule connection between coaches, entrance and exit by doorways in the end vestibules only. Weight, including Westinghouse and vacuum brakes, steam heating and electric lighting, 210 tons; 60 first and 184 third.

Waggons.

Standard Open Goods Waggons—17 ft. long over headstocks, 8 ft. 6 ins. over all, body 3 ft. 1½ in. deep; load, 12 tons; tare, 6½ tons.

Standard Covered Goods Waggons—17 ft. long over headstocks, by 8 ft. 6 ins. wide over all, body 7 ft. 10 ins. high inside; load, 12 tons; tare, 7 tons.

Bogie Covered Goods Waggon fitted with continuous Brakes—37 ft. long over headstocks, 8 ft. 6 ins. wide over all, 7 ft. 10 ins. high inside; load, 25 tons; tare, 15 tons.

Standard Hopper Coal Waggon—20 ft. long over headstocks by 8 ft. wide over all, body 6 ft. deep; load, 23 tons; tare, 9 tons.

Bogie Hopper Coal Waggon—36 ft. long over headstocks by 8 ft. wide over all, body 6 ft. deep; load, 40 tons; tare, 16½ tons.

Bogie Waggon with 5 Bolsters—46 ft. long over headstocks.

34 ft. Bogie C/S—7 ft. 11 ins. width over bolsters, 7 ft. 3 ins. between removable stanchions; load, 40 tons; tare, 18 tons 9 cwts.

Maximum weight of Goods and Mineral Train.—This varies according to the gradient on each section of the road, and according to the class of engine employed to work the traffic. On level sections the maximum load is about 1,100 tons, or about 650 tons net.

CALEDONIAN RAILWAY.

Carriages.

The coaching stock of this Company consists of carriages with 68 ft., 65 ft., and 57 ft. bodies, which are 9 ft. wide The 68 ft. length is only used for the third class ordinary compartment carriages, being seated for six-a-side, which with eleven compartments gives a total seating accommodation for 132 passengers. The 65 ft. length is used for first class ordinary, third class corridor, brake third and brake composite ordinary, and corridor, and composite ordinary and corridor. The ordinary first class has nine compartments for four-a-side, seating seventy-two passengers in all. The third class corridor has nine compartments seated for four-a-side, seventy-two passengers in all. Brake third ordinary and corridor vary from five to eight compartments and are seated for six-a-side ordinary and four-a-side corridor. Composites and brake composites vary a great deal in the arrangement of the compartments, the ordinary composites having ten and the corridor composites eight compartments. The firsts are all seated four-a-side ordinary and three-a-side corridor. The weights of these carriages vary from 37 to 38¼ tons, and they are each carried on two six-wheeled bogies.

The 57 ft. carriages have eight compartments in the thirds, and six in the brake thirds. Composites vary according to the requirements. The seating accommodation is four-a-side third corridor and six-a-side ordinary, with three-a-side first corridor and four-a-side ordinary. The weights of these carriages vary from 30 to 33⅓ tons.

All the trains are electric lighted and steam heated, and corridor trains have lavatory accommodation.

Waggons.

The stock for goods and mineral trains consists of 16-ton mineral waggons, 16-ton pig-iron waggons, 10-ton covered goods vans fitted with dual brake, 12-ton combination brake and goods vans, 10-ton meat vans, 35-ton bogie rail waggons, and 20-ton goods brake vans.

Average trains are about 500 tons gross, although trains of sixty waggons of about 900 tons gross are taken by the heaviest mineral engines.

Recent Developments in Carriage and Waggon Stock.

No very radical departures have been made in carriage and waggon stock on British railways, but in the United States steel is being used to some extent for passenger and freight car bodies. On British railways some trials are being made with galvanised steel plates of about $\frac{1}{10}$ in. for panels of carriages, but anything approaching an all-steel construction for bodies is very much heavier than with wood. On account of the doors with the compartment system, it is not possible to make use of the side of the body as a girder, as in the open American cars with end doors.

Several railways—the G.N.R., G.C.R., S.E. & C.R.—use the American type of automatic coupling and vestibule for some of their main-line trains. In order that these vehicles can be attached to ordinary stock, the coupler is hinged and can be dropped down, exposing a hook for screw coupling. Side buffers are provided, and these have a loose sleeve which can be removed to allow the buffers to be pushed back when the automatic coupling and vestibule with central buffer are in use.

Pullman cars of the American type are extensively used on the S.E. & C.R. and L.B. & S.C.R., and to a lesser extent on the G.E.R., Caledonian, and Metropolitan Railways. Mr. Gresley's twin coaches, as used on the G.N.R., consist of a pair of bodies hinged together. The outer ends rest on bogies in the usual way, but there is only one bogie for the inner ends, the bogie pin being at the hinge between the coaches. A flexible gangway connects the two bodies. This system has been extended to complete trains, so that a set train of five coaches has only six bogies.

The high-capacity bogie waggon makes but slow progress on British railways, owing to the lack of terminal facilities. The tendency is to build 4-wheel waggons of 12, 15, or 20 tons capacity. The fitting of a continuous brake to goods trains is limited to special trains for perishables, ballast, etc. Its more general application is retarded by the presence of a large number of private owners' waggons, the uncertainty caused by the existence of two brake systems, and the high capital costs involved.

A very simple form of self-contained buffer is now used by several railways. It consists of a hollow cast-steel casing and plunger containing a helical spring; this butts directly against the headstock, and initial compression in the spring is obtained in bolting down the casing to headstock.

See also 'All-metal Cars for British Railways,' Vol. CCVIII. (April 1921), *Proceedings Inst. C.E.*

Axle Boxes.

These are usually of cast iron: for carriages oil boxes are universal, and a large number of new waggons are now being fitted with them instead of grease boxes. An oil reservoir in the bottom of the box conveys oil by capillary attraction, either by cotton-waste packing or by means of a worsted pad with tail trimmings supported on springs. The bearing or 'brass' is of gun-metal, or gun-metal lined with white metal. A leather-faced dust shield prevents dirt or water creeping in at the back of the box.

Wheels.

For carriages the wheel with wooden centre, once universal, has now been superseded to a large extent by a steel disc centre of slightly dished form, on which is shrunk a steel tyre having a lip on outside, and secured by retaining ring inside. Tyres are 5 ins. wide and are coned 1 in 20. In order to ensure smooth running, all carriage wheels are carefully balanced. Each pair of wheels is placed on a machine, the journals resting in bearings mounted on springs. When the wheels are revolved at high speed any irregularity in the running can be detected, and a correction made by fastening small plates to the inside of the wheel, near circumference, so that smooth running results.

Wood centres must be bonded by a copper strip between tyre and hub, so as to conduct electric current from rail to rail for operating signalling appliances. Tyre shrinkages are $\frac{3}{16}$ in. for wood centres, and about $\frac{3}{64}$ in. for steel centres.

Waggon wheels are made in a variety of ways. The bossed spoke wheel consists of spokes made from flat bar bent into triangular shape. These are placed together in a mould and a cast-iron boss is cast round them. The outer ends are then welded together to form a solid rim. Instead of casting a boss, it may be forged by placing two discs brought to welding heat on either side of the spokes, and forcing them together in a powerful press. Spoked wheels have also been made by forging spoke bars and building up a wheel. But this has been largely superseded by a cast-steel spoke wheel. A few wheels are being made with steel disc centres, and there are some solid cast-iron wheels with chilled treads now running on British railways. These are on waggons originally built for war service in France.

Journals of axles are sometimes case-hardened, but very good results can be obtained by the simple process of burnishing in the lathe. After the journal is machined, a tool having a small roller at the end is fixed in the slide rest and the journal is rolled all over with considerable pressure; this closes all the pores and leaves a hard, bright surface.

Springs.

Bearing springs are usually 3½ ins. wide for carriages, and 4 ins. for waggons, with plates ⅜ to ½ in. thick, approximately.

If S = span in inches ; b = breadth of plates in inches ; t = thickness of plates in sixteenths of an inch ; n = number of plates ; L = safe load in tons ; D = deflection in sixteenths of an inch per ton of load,

$$n = \frac{17SL}{bt^2}; \quad L = \frac{bt^2n}{17S}; \quad D = \frac{2S^3}{t^3bn}.$$

Buffer springs are largely made of rubber, and are formed of rubber discs 2½ to 3 ins. thick, placed between 6 or 8 metal discs.

For 'Helical Springs' see p. 608.

Couplings.

Draw bars should be 1¾ ins. diameter ; they should be made from the same quality of iron as the hooks, giving 23 per cent. elongation in 4 ins. and 23 tons per sq. in. ultimate stress. Area of end of eye = area of two sides × 1·2.

Couplings should be made of high-class chain-iron (giving about 35 per cent. elongation in 4 ins., and 45 per cent. reduction in area, with a tensile strength of 22 to 23 tons per sq. in.) ; when side-welded they should stand 35 to 40 tons total stress, equal to 11·7 to 13·4 tons per sq. in. Standard diameter = 1⅝ in.

Screw couplings are of wrought iron, or sometimes of steel (B.S.S. 9B).

Draw hooks should be of best selected wrought-iron scrap, giving about 23 per cent. elongation in 4 ins., and 23 tons per sq. in. ultimate stress. If stamped out, the grain of the iron should be kept running with the hook, an important point sometimes overlooked in second-rate work.

LIGHTING AND HEATING RAILWAY CARRIAGES.

Stone's System of Electric Lighting for Railway Carriages.

In this system, fig. 24, the dynamo for producing the electric current is suspended from the under-frame of the carriage so that its pulley is at approximately the same level as the pulley on the axle, from which it is driven direct by means of a belt.

Speed of Pulley on Axle of Motor (representing Axle of Railway Carriage).	Equivalent Speed of Trainin Miles per Hour (approximate).	Speed of Dynamo, Revolutions per Minute.	Equivalent Speed of Dynamo if no Slip were to take place.	Output of Dynamo. Amperes.
100 Revs. per Minute	*12*	500	*500*	0
150	*18*	750	*750*	6
175	*21*	870	*875*	16
195	*23*	900	*975*	18½
225	*27*	915	*1,125*	20
275	*33*	915	*1,375*	20
325	*39*	915	*1,625*	20
375	*45*	915	*1,875*	20
450	*54*	915	*2,250*	20
600	*72*	915	*3,000*	20

However the speed of the train may vary, after a certain predetermined limit has been reached, *the dynamo always runs at a uniform speed and consequently always produces practically the same amount of electricity.* This result is obtained by suspending the dynamo by one corner of its frame by means of an adjustable link, so that the driving belt draws the dynamo out of the diagonal position in which it would naturally hang, thus putting a definite tension on the belt just sufficient to absorb power equivalent to the amount of electricity required When the pull on the belt (owing to increase in speed of the train) exceeds the weight on the belt, due to the one-sided suspension of the dynamo, the latter is automatically drawn towards the driving pulley on the axle, thus allowing the belt to slip while the armature continues to revolve at its normal speed. That the arrangement is an effectual one is shown by the above table.

The latest developments in the system includes the introduction of the firm's 'Liliput' dynamo compactly built on modern lines and provided with ball bearings throughout, a special feature being that all the parts are very easily accessible for inspection or removal. The armature is of the drum wound type with former wound coils, the machine itself being shunt wound.

The centrifugally operated switchgear embodied in the older dynamos is omitted from the 'Liliput' machine, the switching being now effected by a separate automatic cut-in and cut-out switch operating on voltage ; and in the case of a double battery system, a 'Pegoud' battery

STONE'S SYSTEM OF ELECTRIC LIGHTING FOR RAILWAY CARRIAGES.

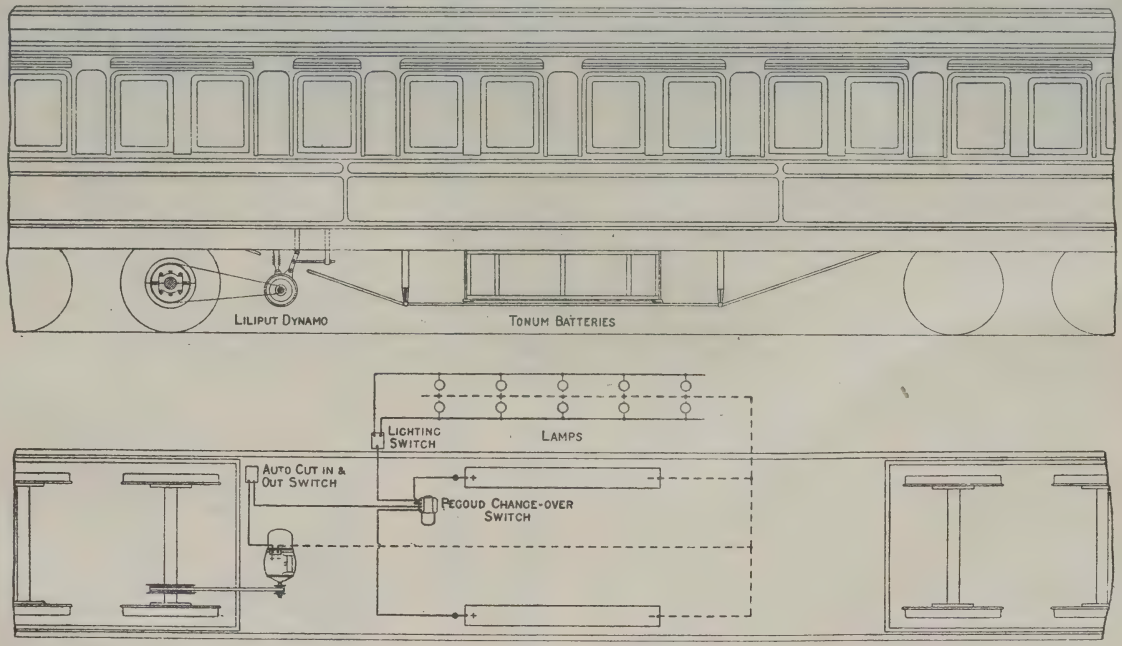

FIG. 24.

change-over switch is included, so as to change over the position of the charging and regulating batteries every time the dynamo switches into circuit.

The ' Lilliput " dynamo (in which is embodied the pole-charging device) is made in two forms, either to run at a constant speed, as described above—the output being controlled by means of a slipping belt—or at a variable speed, that is, the speed of the dynamo following the speed of the train, the output remaining constant at all speeds, and as the lamps are switched ' on ' or ' off ' so the dynamo output increases or decreases according to the demand.

' Tonum ' batteries are used, with either Plante or pasted positive plates. When a single battery is installed, the battery has twice as many positive plates as is the case when a double battery system is installed, and as the latter, i.e., a double battery system, gives the best regulation and is more reliable in working, it is always recommended.

The accumulator being always in connection with the lamps causes the light to be absolutely steady, acting as a regulator to absorb any excess of current generated by the dynamo.

The working parts of the dynamo are enclosed in a movable, but duct-proof casing.

A switch is provided to each carriage so that the lights can be either fully on or entirely off, or where there are tunnels, and the light is required in the daytime, half the lights may be used. When the lamps are not alight, the current is being stored in the accumulator.

The whole of the apparatus is of British manufacture and made in London, the system being largely adopted by the leading railway companies throughout the world.

An essential factor in the success of a train-lighting system is a reliable secondary battery which will in addition to meeting the variable demands for energy, be able to withstand the vibration and shock to which cells carried on a coach are necessarily subjected. Very successful results have been achieved by the use of the *Fuller Block Accumulator*, in which the usual plate form of electrode is departed from, a grid block of triangular form being employed instead. The blocks are grouped together to form a cylinder, positive and negative sections being insulated from each other by special separators and the whole bound tightly together. Recent tests show that this type of cell, amongst other purposes is peculiarly suitable for train lighting. The cells will stand short circuiting without damage, will withstand rough usage, and have the property of retaining their charge for long periods without appreciable fall in voltage. They are also singularly free from sulphating, and in general, from all other defects to which plate cells are liable. These cells are suitable for use with any of the train-lighting systems in use to-day, and it is claimed that their use will materially reduce the working costs in connection with the lighting systems of the railways where they are installed.

Heating Railway Carriages by Steam.

With coal of such a quality that it produces 7½ times its own weight of steam in the locomotive boiler, the average consumption of coal for the three coldest months should not exceed about 6½ lbs. per axle per hour.

Westinghouse System.

In the Westinghouse system of heating, steam at atmospheric pressure is used in the only heaters, and the temperature of the heaters is thus maintained equal throughout the train.

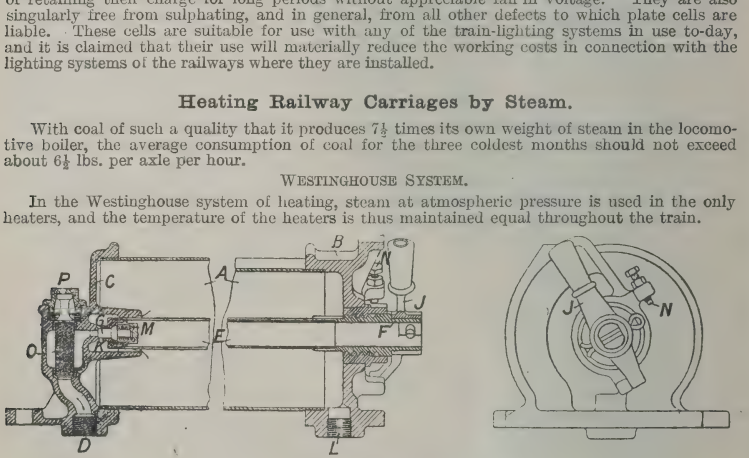

Fig. 25.—Westinghouse Patent Heater.

Fig. 25 shows a Westinghouse patent heater. It consists of a tube A, with caps B and C. Steam from the main pipe enters at C. E is a tube of an alloy having a high ratio of expansion. At one end is attached the screwed socket F, which can be turned through 90° by the handle J. At the other end is the valve G. With the handle at ' on ' position, and the heater cold, valve G stands away from the seat K. Steam enters and fills the heater, while the water of condensation escapes to the atmosphere at L. As tube E becomes hot, it expands more than tube A, and valve G therefore approaches the seat K, and when it reaches a predetermined temperature the valve G closes the steam inlet. The heater then cools slightly, tube E contracts, and allows a further quantity of steam to enter the heater. The temperature of the heater is thus maintained constant.

If it is desired to lower the temperature of the heater, handle J is moved towards the ' off ' position, thus bringing valve G nearer seat K. The tube E then does not require to expand so

much to close the steam inlet, and steam is cut off when the heater reaches a lower temperature than before. The temperature of the heater can therefore be regulated to a nicety by means of the handle J. If the handle is moved right over to the 'OFF' position the valve G is brought on to the seat K, thus completely shutting off the steam.

It will therefore be seen that a variation of pressure in the main pipe does not affect the temperature of the heater, which is determined by the position of the handle J and automatically maintained constant. As the temperature in the heater cannot exceed 212° the steam is never at more than atmospheric pressure.

This system is now in use in many countries in various parts of the world, and has maintained a comfortable temperature in carriages exposed to an outside temperature of 36° F. below zero.

BRAKES.

Action of Brakes.

f = proportion which resistance produced by brakes bears to weight of train.
v = speed in feet per second.
V = speed in miles per hour.

Distance in feet in which the train is stopped on level $= \frac{v^2}{64{\cdot}4f} = \frac{V^2}{30f}$.

Brakes self-acting on all the wheels, $f = {\cdot}14$.
Ordinary brakes worked by hand in brake-vans, $f = {\cdot}031$ to ${\cdot}023$.

On gradient *ascending* 1 in n, resistance $= f + \frac{1}{n}$.

On gradient *descending* 1 in n, resistance $= f - \frac{1}{n}$.

Distance in feet for stopping $= \frac{f \times \text{distance on level}}{f \pm \frac{1}{n}}$.

Power required by Brakes.

The following results have been obtained as regards consumption of energy with different kinds of air brakes:—1. On city lines, the consumption of energy for excentric compressors was 41·5 watt-hours per car kilom. (66·4 watt-hours per car mile); with geared compressors, 31·2 watt-hours per car kilom. (49·9 watt-hours per car mile); and with motor compressors, 16·16 watt-hours per car kilom. (25·86 watt-hours per car mile). 2. On suburban lines, the consumption for excentric compressors was 22·8 watt-hours per car kilom. (36·5 watt-hours per car mile); with geared compressors, 14·6 watt-hours per car kilom. (23·4 watt-hours per car mile); and with motor compressors, 6·32 watt-hours per car kilom. (10·11 watt-hours per car mile).

The Westinghouse Automatic Brake.

The Westinghouse automatic brake is continuous throughout the train and is operated by compressed air furnished by the pump and stored in the main reservoir on the engine. This compressed air is fed by the driver's brake valve into the train pipe and, past the triple valves, into the auxiliary reservoir on each vehicle.

The brake is applied by reducing the pressure in the train pipe, which causes the pistons of the triple valve to move and permit some of the compressed air stored in the auxiliary reservoirs to pass to the brake cylinders, the pistons of which are forced outwards, applying the brake blocks to the wheels.

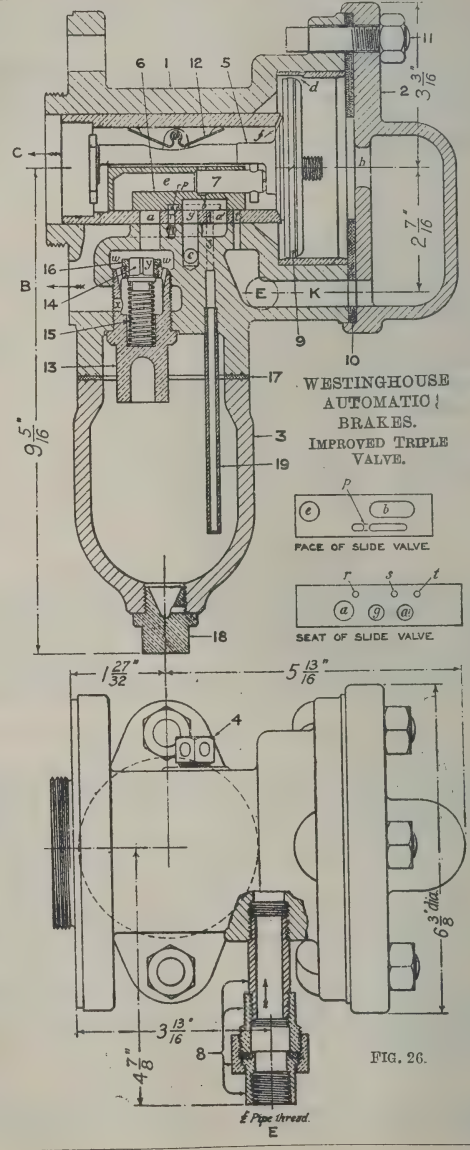
The brake is released by restoring the air pressure in the train pipe, which causes the triple valves to close the communication between auxiliary reservoirs and brake cylinders and open a port from the brake cylinder to the atmosphere, through which the compressed air escapes from the cylinder. The spring in the cylinder can then push back the piston and withdraw the blocks from the wheels.

The brakes are usually applied by the driver, or in cases of emergency by the guard, but a break-away, or rupture of a hose coupling, or other accident causing an escape of air from the train pipe, also immediately applies the brakes.

It is recommended that a pressure of 90 lbs. per sq. in. be maintained in the main reservoir, and 70 lbs. per sq. in. in the train pipe.

Improved Triple Valve.

This valve has been designed to give a closer approach to simultaneous action of all the triple valves in a train than heretofore. As shown in fig. 26 the valve is in the release position



WESTINGHOUSE AUTOMATIC BRAKES.
IMPROVED TRIPLE VALVE.
FACE OF SLIDE VALVE.
SEAT OF SLIDE VALVE.
E Pipe thread.

FIG. 26.

WESTINGHOUSE AUTOMATIC BRAKE.
DRIVER'S EQUALISING BRAKE VALVE.

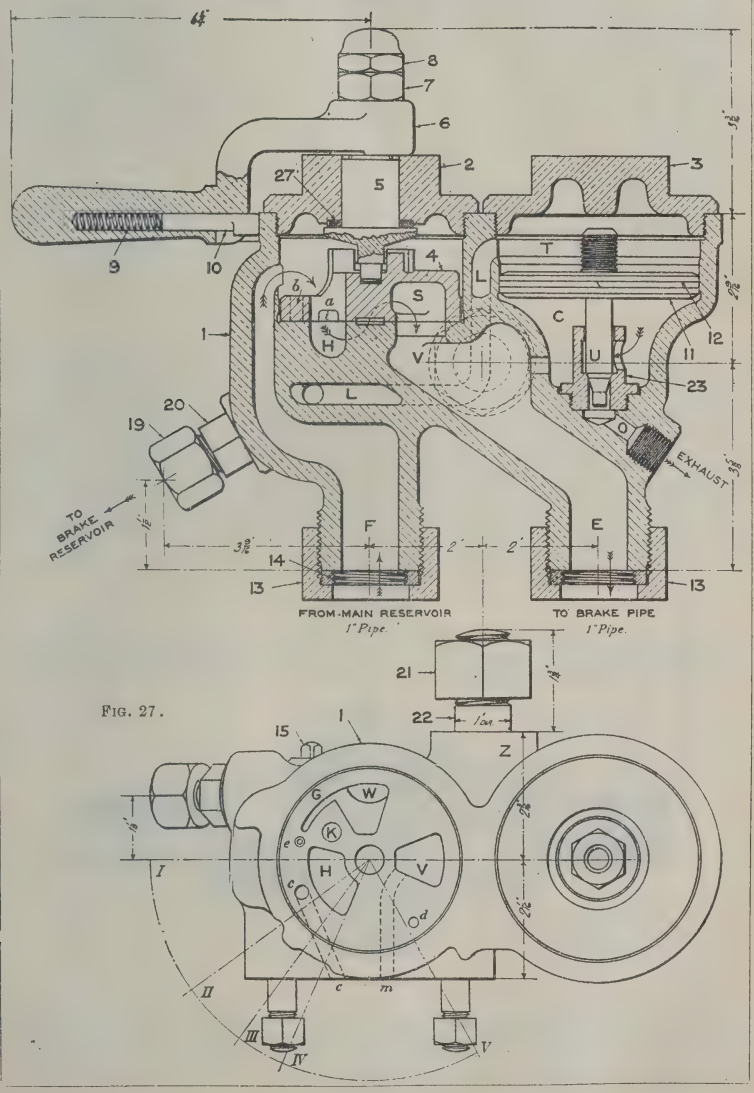


FIG. 27.

and the bulb is open to the atmosphere. When the slide valve 6 is moved in applying the brakes, the bulb 3 is closed to the atmosphere and opened to the train pipe by the cavity *p* and port *s* shown in dotted lines. The local reductions of train pipe pressure thereby produced by the forward triples in a train cause an earlier action of the rearward triple valves, which results in a more nearly simultaneous braking effect being produced throughout the train in every case of first setting the brakes than heretofore, with a smoother and more efficient brake service generally.

A further improvement, also tending to smooth and even action of all the brakes, is shown in the passage leading from port *a* in the seat of the slide valve 6 to the brake cylinder at B. It consists of a removable plug 13, perforated with holes *w* and *x*, which are always open, and an additional hole *y* carrying an automatic check valve 14, supported by a spring 15. It is so arranged that, when the brakes are first set, the automatic valve is opened against the spring resistance by the excess of air pressure above it, so that the hole *x* controls the rate of flow of air to the brake cylinder: as the air pressure on the under side of the valve increases, the spring closes the valve, when the smaller holes *w* control the rate of flow to the brake cylinder. The diameters of the regulating holes *w* and *x* are made proportional to the diameter of the brake cylinder with which the triple valve is to be used. By changing these perforating plugs, the same pattern of valve is thereby suited to cylinders of various sizes.

The bulb at the bottom of the triple valve is made in different sizes, proportioned in content to the volume of the train pipe of the vehicle on which the valve is to be used.

A separate passage a^1 is provided in the triple valve body from brake cylinder to slide valve 6, for the air to escape from the brake cylinder on releasing the brakes. The rate of release is controlled, as heretofore, by a nipple screwed into the outlet hole *c* in the triple valve body.

Driver's Equalising Brake Valve.

The principle of this brake valve, fig. 27, is, not to allow the driver in ordinary applications of the brakes to discharge air directly from the main pipe, but from a small reservoir connected with chamber T of the valve. The reduction of air pressure, thus effected in the reservoir, is then at once automatically and properly repeated in the main pipe by means of a small equalising piston, 11, placed between the air in the chamber T, and that in the main pipe E. The piston moves in accordance with the variations in pressure above and below it, and governs an exhaust valve U in such a manner that the air pressure in the main pipe must always equalise with that in the small reservoir connected with the valve chamber T. Even if the exhaust of air from the brake valve reservoir is abruptly stopped by the driver, the discharge valve U is always gradually closed by the piston, when equilibrium of pressure is established throughout the train. The equalising device, therefore, will under all circumstances provide for a uniform reduction of the pressure in the main brake pipe, thus insuring a uniform application of the brakes to all the vehicles in the train.

The compression of air is effected by a pump (Westinghouse), a description of which is given in Section XXII.

Pipe Couplings.

In the connecting-pipe *coupling*, which is shown by fig. 28, the two halves of couplings, 1, 1, are exactly alike, and an air-tight joint is formed by means of the rubber packing-ring, 3, in each, which rings face each other when the couplings are united. The air-pressure in the

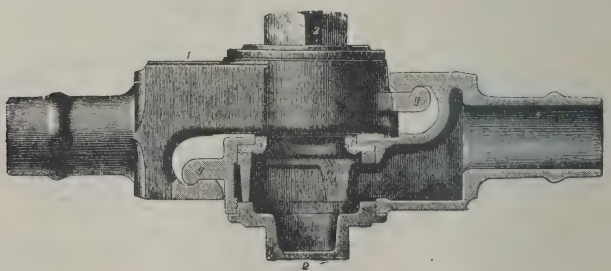

FIG. 28.

couplings tends to force these rings towards one another, so that the joint becomes tighter with increase of pressure. The tendency of the air-pressure in the couplings is also to force them apart in a direction at a right angle to the line of the india-rubber hose-pipes, and, consequently the greater the pressure, the more firmly are the couplings held together by the projecting piece, *g*,

of each coupling, which fits in a corresponding groove of the other coupling. No damage is done if the couplings be drawn apart forcibly by the separation of the train, as the rubber rings, 3, 3, are forced into their respective couplings far enough to permit the projections to disengage from their grooves. These couplings are united by simply placing them face to face at right angles, the stop-pins being on the under side, and then turning the projection of the one into the groove of the other.

The Vacuum Automatic Brake.

In this brake an ejector placed upon the engine exhausts the air (to a vacuum of 20 to 24 inches) out of the continuous pipe and the cylinders. The brake is applied by the admission of air into the train pipe, and released by the withdrawal of the same through the ejector. The brake is self-acting in the case of an accidental parting of the train.

The brake-cylinder (figs. 29 and 30) is self-contained in the vacuum-chamber as applied to carriages, and is the only fitting required. The piston fits freely in the cylinder, and is packed by a rolling rubber ring, which, when the piston moves, rolls between it and the cylinder, making a perfect packing without friction. The piston-rod is coated with brass, and works through a brass bush, and a packing rubber prevents air passing the rod. At the bottom of the cylinder is attached the ball-valve, the branch of which is connected by a small hose-pipe to the train pipe. This valve is of the most simple construction, as there is only one moving piece, and that being a small brass ball, having a rolling action in a horizontal position, has consequently no friction. A spindle with release lever (not shown in the figures) is added for the purpose of withdrawing the ball from its seat when it is required to release the brake by hand. This spindle is made air-tight by a small diaphragm, the pressure on which when a vacuum is created pulls in the spindle and allows the ball to go freely to its seat.

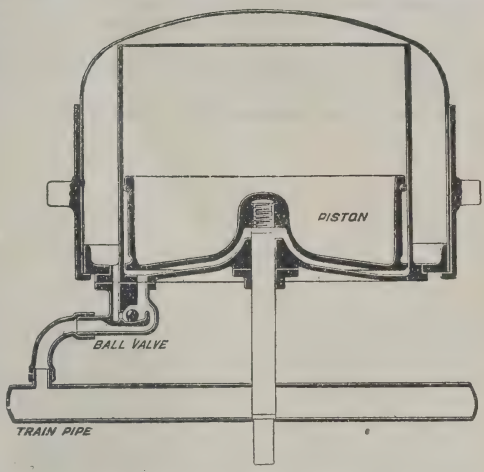

FIG. 29. Vacuum Automatic Brake. Brake off. Representing position of piston and valve when a vacuum is created and the brake is off.

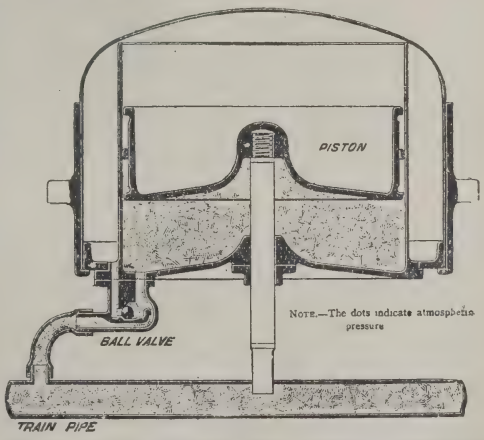

FIG. 30. Vacuum Automatic Brake. Brake on. Representing position of piston and valve when the brake is applied by the admission of air to the train pipe. The ball is held tightly to its seating, and preserves the vacuum on the top side of the piston, which is raised by the atmospheric pressure below it.

The action of the cylinder is as follows: The air is drawn out through the train pipe from the bottom of the piston direct, and from the top by passing the ball, which it forces up the

incline of the spindle; when all the air is withdrawn the ball rolls down the incline and on to its seating. To apply the brake, the air is let into the train pipe, and it then passes to the under side of the piston, and, being prevented from entering to the top by the ball, lifts the piston, and so applies the brakes with any amount of force according to the quantity of air let in.

The couplings are extremely simple; each consists of a pair of castings exactly alike, with horns top and bottom. It is impossible to couple them wrongly. To couple they are lifted up sufficiently high to enable the bottom horns to be placed together, and then lowered, the top lug of one being placed in the slot of the other. To uncouple it is simply necessary to raise the couplings, when they will separate.

For Board of Trade Regulations with reference to brakes, see Part IV., page 661.

SECTION XII

PART III

RAILWAY SIGNALS.

(Revised and amplified by H. Raynar Wilson.)

Pneumatic Railway Signals.

In this system of Railway Signals (the British Pneumatic Railway Signal Company), every movement is accomplished by air pressure (normally 15 lbs. per square inch); nothing depends upon gravity or springs, or on withdrawal or reduction of pressure; except when a switch or a signal is being moved, or an indication is being given, all operating and indicating pipes are subject to atmospheric pressure and no more; the final portion of the stroke of the 'lever' is automatic, requiring no effort or care on the part of the operator.

The pressure used to move switches and signals is 15 lbs. per square inch, that for conveying indications only 7 lbs. A switch 500 feet from the signal cabin is moved, and the return indication received back in the cabin within a few seconds from the movement of the switch.

A signal is held in the 'all clear' position by continued pressure of air in the pipe leading from the cabin to the signal; absence or failure of power will always leave the signal in the 'stop' or 'danger' position.

The Diaphragm Valve.

This valve performs a function analogous to that of the electro-magnetic relay in electrical apparatus. It is actuated by a comparatively weak force (air at 7 lbs. pressure per square inch), but by its action opens a valve which liberates air at 15 lbs. per square inch to perform any desired work. The work to be done is to lift the stem of the vertically placed cylindrical valve in the upper part of the case; and this is accomplished by introducing pneumatic pressure on the under side of the horizontal rubber diaphragm in the lower part. This diaphragm is circular, 8 inches in diameter, and is quickly responsive to low pressure. The pistons and openings are so proportioned that a movement of the diaphragm of only one-quarter of an inch is found sufficient for all purposes. Two diaphragm valves at the switch control the switch cylinder, the piston of which moves the switch. Two similar valves at the foot of the semaphore signal post control the signal arm in like manner.

The Control Lever.

This lever, L, fig. 1, has two slots, Z and Q, of the shape shown. Below each lever are two cylinders, I I'. The rods of the pistons sliding in these cylinders carry rollers which are guided in the slot Q. The locking bar H also carries a roller at its upper extremity, guided in the slot Z. If the handle h (corresponding to a lever in the ordinary mechanical locking-frame) be pulled, it will move until the roller on the piston rod of I' abuts against the shoulder T of the slot, thus limiting the outward movement. By this operation a slide valve V has been moved. The slide valve is so constructed that in two of its positions a port in the valve opens communication between the supply pipe of the apparatus and one or other of the two pipes O and P, but in all other positions of the valve these two pipes are connected to the atmosphere through the exhaust ports of the valve. In the position of the handle where the roller of piston rod I' has, as explained, come against T, the valve V has opened a passage between pipe C (the supply pipe) and pipe P; at the same time, owing to the shape of the slot Z, the locking bar, H, has completed half only of its vertical movement; this half movement has, however, interlocked levers which were free in the original position of the handle h, but those levers which correspond to the extreme movement of h are still held locked; the mechanical arrangement of the interlocking bars possesses no special feature.

General Action.

The opening of a passage between C and P (on the movement of V) allows the compressed air from the supply pipe to pass through pipe P to diaphragm valve R', and to actuate the latter; this allows air from the supply pipe connected to R' to enter the right-hand side of cylinder

C and to move the piston of C; the rod of this piston, being attached directly to the slotted plate M, moves the latter to the left. This plate M has in it two slots, N and N′, and two projections, S, S′; these projections lock the switch in its two extreme positions by means of a lock bar Y, fixed to the switch, and having notches to receive the projections.

The switch bar W carries at its extremity a roller guided in the slot N; this slot has two parts parallel to the axis of the cylinder, united by a diagonal part. Another slot N′ in the motion plate is similar in general form to N; this slot is for the purpose of moving an indication bar connected to a valve D: in the position shown in the figure, this valve is so set that its port

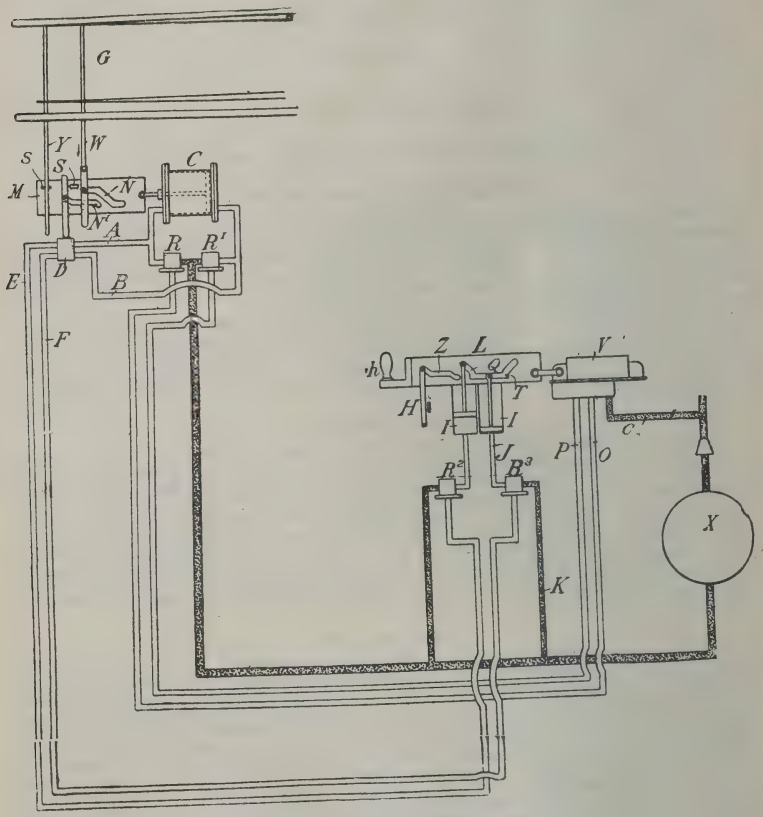

FIG. 1.—The Control Lever for Points.

forms a communication between pipe A and pipe E; in the other extreme position of the valve (i.e., when it is moved by plate M being pushed over to the extreme left) communication is established between pipe B and pipe F.

As soon as the piston in cylinder C begins to move to the left the indication valve will be moved to its middle position by the incline of the slot N′, so that all communication between pipes A, E, B, and F is shut off; at the same time the switch G will be unlocked, as the projection S′ will move out of the notch in the lock bar Y. This first part of the piston movement will have no effect upon the switch, as the roller on the switch bar will be simply guided in the parallel

part of slot N; this part of the movement is also utilised to start the 'detector bar,' which is connected to the motion plate by rods and a lever. As soon as the switch has been unlocked, the continued movement of the piston will move the switch over by means of the diagonal part of the slot N and the switch bar. During this time the indication valve will remain stationary. After the switch has been entirely reversed, the projection S' will enter another notch in locking bar Y, and the moving and locking of the switch will have been accomplished. The last part of the stroke of the piston will now move the indication valve D to its extreme position, so that a communication will be established between pipes B and F; as the diaphragm valve R' remains open, air will enter pipe F from pipe B through the indication valve. This pipe F, as above stated, returns to the signal box apparatus, and ends under the diaphragm of another relay valve R², precisely similar in construction to the one already described. The air pressure through F will open this valve and establish communication between a branch K of the main supply and a pipe J which leads into the cylinder I'. It will be remembered that all these movements have taken place because of the pulling out of the lever *h* to the extent limited by the roller on the piston of the cylinder I'. When air now enters under this piston, the roller will be lifted clear of the shoulder T, will enter the diagonal portion of the slot in the lever, and, by the continued action of the upward pressure, will push this lever out still farther until its stroke is completed and the roller abuts against the end of the slot. This complementary part of the stroke of the lever is accomplished automatically, that is to say, the operator is not obliged to wait for the indication to return to the machine before he grasps the following lever, but he can immediately place his hand on this lever, which will be freed as soon as the indication will have completed the stroke of the first one. It will be seen that the movement of the interlocking bar H is completed by the indication stroke through the inclined part of the slot Z. When *h* has completed its outward movement, then valve V will be in its extreme position in which its exhaust port will connect the pipe P with the atmosphere. The air under pressure which filled this pipe, and held the relay valve R' open, will therefore exhaust, and the spring of the relay valve will close the latter, shutting off the main supply and opening an exhaust passage through which the air in the cylinder C can escape. All parts will again be in a normal position of rest, in which all the pipes, except the main supply and the supply to the signal box apparatus, are open to the atmosphere and are subjected to no pressure.

In order to move the switch back to its original position, the operation is precisely the same, only the other cylinder I and the other relays R and R² will be in action as well as the corresponding set of operating pipes.

It will be seen that the indication—that is to say, the return of air to the machine in order to complete the stroke of the lever and of the interlocking bar—is imperative as well as automatic. If from any cause whatever the switch has not moved over completely, or has not been locked in position, the indication valve will not establish the communication above described, no indication will be received in the cabin, and the levers interlocked with this switch lever cannot be pulled, so that no signal can be lowered and no conflicting switch moved.

In order to operate the semaphore signals, the arrangement is similar to that of the switch points, except that the indication, which, in the points, must be given for both positions, is only given for the normal or danger position of the signals. In resetting the signal to danger, it is necessary to have an indication in order to be assured of the fact that the signal has again reached its horizontal position. Instead of having an indication slide valve as in the switch movement, the indication arrangement in this case is a valve constructed precisely like the relay valves, actuated, however, by a lever (whose extremity abuts against the valve stem) instead of by a diaphragm. When the signal is in its normal or danger position this indication valve is open, thus establishing communication between the supply pipes.

As in the switch movement, if the signal does not go back to danger from any cause whatever, no indication will be given, and the interlocking on the machine will prevent conflicting lever movements.

The whole arrangement is such that it is impossible to move a switch or a signal if any of the other parts corresponding to it are not in the correct position. Any derangement of the switches or signals which would prevent regular operation is immediately indicated in the cabin by the fact that the lever does not complete its stroke.

The diameter of the switch cylinder is 10 ins.; that of the signal cylinder 5 ins. The main supply pipe consists of 2-in. pipe at its origin, and the diameter of the pipe diminishes towards the end of the yard. The operating and indicating pipes are all ½ in. The branches from the main supply to the relays are ¾-in. pipes. The distance between the levers centre to centre of handles is 3 ins.

For a cabin of 100 levers, under average conditions, the compressor should have a capacity of 100 feet of free air per minute. This capacity is governed, not by the number of levers in the cabin, but by the maximum number of train movements occurring in a given time.

Connected with three (Basingstoke-Woking, Clapham Junction, Guide Bridge) installations of low-pressure pneumatic signalling there are stretches of main line controlled by automatic signals, the operation of which is the same as in the power plants except that the signals are controlled by track-circuits instead of by the movements of a signalman.

The British Pneumatic Railway Signal Company has also an all-electric system for operating points and signals which is installed in six signal-boxes in a large shunting yard (Immingham); passenger trains do not, however, run regularly over the lines so controlled.

WESTINGHOUSE ELECTRO-PNEUMATIC RAILWAY SIGNALLING SYSTEM.

This consists essentially of electrical circuits working in conjunction with a compressed air supply. The electrical system connects the signalman's levers at the cabin with the points and signals, whereby instantaneous response of the signals and points to the motions of the levers is secured, and also an instantaneous 'indication' of the movements of the points and signals is returned to the locking frame. The compressed air of about 60 lbs. per sq. in. pressure serves as the actual power moving the signals and points. The levers in the signal cabin are merely small electrical switches, and they involve no heavy labour on the part of the signalman for their operation. The locking frame, the levers of which are closer together and far less in number than those in the hand system, is provided with two kinds of interlocking — a mechanical system and an electrical system. The mechanical interlocking is practically identical with that used in hand-power signalling systems, excepting, of course, that the parts are very much lighter. The electrical locking consists of a series of electro-magnets in the indication circuits from the signals and points; the armatures of these magnets engage with projecting lugs or sectors fitted to the shafts of the levers. By means of this combination of electrical and mechanical locking, the many complicated problems of special locking required by modern methods of signalling are easily and successfully solved. The electrical contacts of the lever shafts, by which the circuits between the battery and the electro-magnetic valves of the point and signal motors are made or broken, consist simply of phosphor-bronze strips, working over contact pieces mounted on an ebonite bushing surrounding the lever shaft. The electric current is usually drawn from a small battery of storage cells, the pressure being about 14 volts. Primary cells are often used, the current required being only about 0·05 ampere per signal or point motor. Small wires made up into cables connect the locking frames with the various point and signal motors.

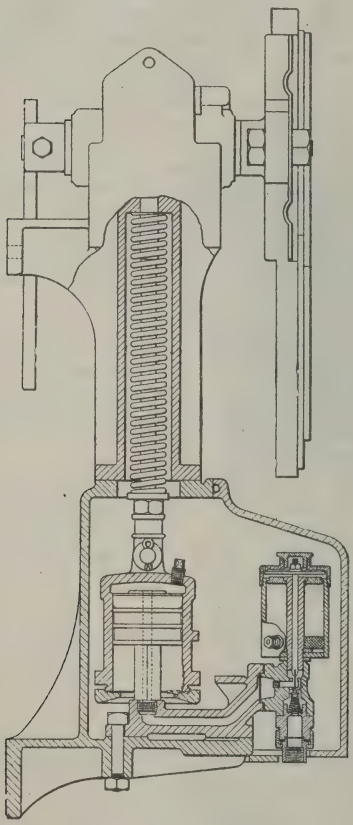

Fig. 2.

The actual work of pulling off a signal or throwing over a set of points is done by a small compressed air-motor fixed close by the signal or point to be operated. The definite, straight line motion of such motors is particularly suitable for the movement of signals and points. The valves controlling the air supply to these motors are opened by small electro-magnets. With this system selection of signals becomes simple, since it is easy to arrange the electrical contacts in such a way that the path of the electric current is made through the signal only which appertains to a route which is set by the movement of certain point levers, and when the signal lever is pulled over that signal only is operated by the electric current: whereas, if other point levers are operated or another

FIG. 4.

route set, the path of the current being changed, another signal is operated when the same signal lever is pulled over.

The pressure of the compressed air used is, as before stated, about 60 lbs. per sq. in. Experience has proved this pressure to be the most suitable for the purpose, having regard to the size of the motors, and the general convenience of installing, operating, and maintaining the system. The quantity of air used does not amount, even at the busiest centres, to more than half a cubic foot of free air per minute per lever.

Signal motors (fig. 2) are fitted on the posts. They are single-acting, the function of the motor being to force the signal arm down to the 'line clear,' or 'off' position. The force of gravity returns the arm to the position of 'danger' when the pneumatic pressure behind the piston of the motor is released. In thus trusting to gravity to replace the signal arm to 'danger' all chances of the arm being held 'off,' owing to the failure of power supply, are eliminated. The upper end of the signal motor cylinder carries the electro-magnet by which the valves controlling the admission and exhaustion of the compressed air are controlled. The signal motor has a cylinder 3 ins. in diameter, and a stroke of 4 ins. The electrical indication circuit breaker of the signal is operated by a lever direct from the signal arm.

The point motor (fig. 3) consists of a double-acting cylinder working horizontally, and is usually installed outside the track, alongside the points. The valve, by which compressed air may be admitted either to one side of the piston or the other, is operated by compressed air behind two small pistons, controlled by electro-magnetic valves similar to those of signal motors. The diameter of the point-motor cylinders varies from 4 to 6 ins., and the piston stroke from $4\frac{1}{2}$ to 8 ins., according to requirements. In the case of a trailing point, the electrical indication circuit breaker is operated by the switch rail opposite to that to which the motor is coupled. In the case of facing points, the circuit-breaker is operated only after the locking-bar and lock are home, thus ensuring the correct position and locking of the points before an indication to that effect can possibly be received at the cabin.

Westinghouse electro-pneumatic signals are also largely used in connection with automatic signalling, both on steam and electric traction roads. For this purpose the running rails are divided into suitable sections or blocks which are electrically insulated from one another: the presence of a train or any vehicle in a block keeping the signals controlling the entrance to that block at danger. The signals are not cleared to admit a second train until the first train has cleared the block by a certain distance, depending upon the braking distance required by a train.

Such installations are largely used in America, there being nearly 10,000 signals of this type in operation. In Great Britain complete installations have been working for several years on the Metropolitan Railway, the Metropolitan District Railway, the London Electric Railways (consisting of the Baker Street and Waterloo; Great Northern, Piccadilly and Brompton; and Charing Cross, Euston and Hampstead Railways), the Central London and the East London Railways. These installations deal with a service of forty trains per hour, and have the additional protection of a train stop at every signal location which automatically applies the brakes on a train should it overrun a signal at danger.

The electro-pneumatic signalling apparatus, both for power-operation of points and signals and for automatic signalling, is manufactured and supplied by the McKenzie, Holland and Westinghouse Power Signal Co. Ltd., of Westminster.

McKENZIE, HOLLAND AND WESTINGHOUSE ALL-ELECTRIC SYSTEM.

For those railway companies which prefer the use of electricity throughout, the same firm has an all-electric system of operation of points and signals which is in successful use.

'CREWE' ALL-ELECTRIC SYSTEM.

The Railway Signal Company, Ltd., are the manufacturers of a system, of which there are several installations on the London and North Western Railway—hence its name—of operating points and signals by electricity.

Fig. 4 illustrates the locking frame, and it will be seen that the levers are in two tiers, those, *a*, in the upper tier taking odd numbers and, generally, working points, and those, *b*, in the lower the even numbers and, generally, working signals. To each lever is connected a down-rod *c* to which, immediately under the signal-box floor, are coupled cranks. These actuate the interlocking tappets in the usual interlocking boxes. At the lower end of the down-rod is connected the switch *d*, the carbon contacts of which join, when the lever is moved, switches *e f* and *g h*, and so cause power to be sent to the points or signal as the case may be.

As in other power-signalling systems, the full stroke of a point lever from normal to reverse and from reverse to normal, and the complete stroke of a signal lever from the 'off' to the 'on' position, cannot be made until an indication is received that the operation set up by the initial movement of the lever has been completed. This, in the 'Crewe' system, is achieved by the check lock *j* attached below the switch. On the check lock *j* are two lugs k^1 k^2 which engage pawls l^1 l^2, the armatures of which can be attracted by the magnets m^1 m^2. When a point lever

is moved, say, from normal to reverse, the down rod is raised and the lug k^2 on the check lock f will then abut against and be stopped by the pawl l^2, but as soon as the current set up by the switches above has done its work, the return indication current energises the magnet m^2, so that the pawl p^2 is attracted and frees lug k^2, consequently the lever can then be pulled the remainder of the stroke. When the points are being restored to normal the down-rod descends and lug k^1 is then stopped by pawl p^1 until magnet m^1 is energised. When the points are reversed the switch d has its contacts on switches e and g, and when normal on switches g and i.

Fig. 5 is a plan and elevation of the lay-out of a pair of facing points. The motor (see also fig. 6), which requires current of 20 amperes and 100 volts, is fixed in a cast-iron box below rail level. The motor a (fig. 6), by means of a worm, drives the worm wheel b, fixed loose on the same shaft as the cam wheel c. Movement is transmitted to the cross shaft by means

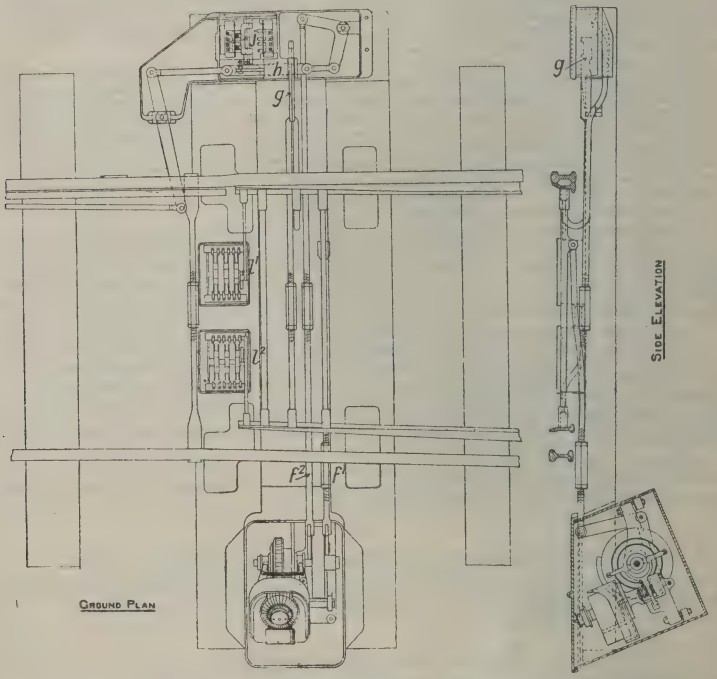

FIG. 5.

of one or other of the clutches d^1 d^2, which are right- and left-handed, so that if the worm wheel turns in one direction the right-handed clutch is engaged, and if in the other direction the left-handed clutch. On either face of the cam wheel c is a cam-shaped slot of irregular contour in which works a roller attached to a crank e. The crank on one side works the points by means of the rod f^1, and the other crank actuates the plunger and locking-bar by means of rod f^2. Each point has an extension g, suitably slotted on the upper side for one position of the points and on the lower side for the other position of the points. Both extensions and, therefore, both switches of the points must be accurate in their position or the plunger h will not pass through them. To the end of the plunger is connected a rod leading to the locking bar. On the upper side of the plunger are guides that move over a short lever and place the contact maker j in or out of contact with the springs k^1 k^2. The latter are connected to the magnets m^1 m^2 of the return indication in fig. 4 and cause pawls l^1 l^2 to be attracted and allow for the down rod c to complete its upward or downward movement and for the switch d to make contact with eg—if an upward movement—or

CREWE ALL-ELECTRIC SYSTEM.

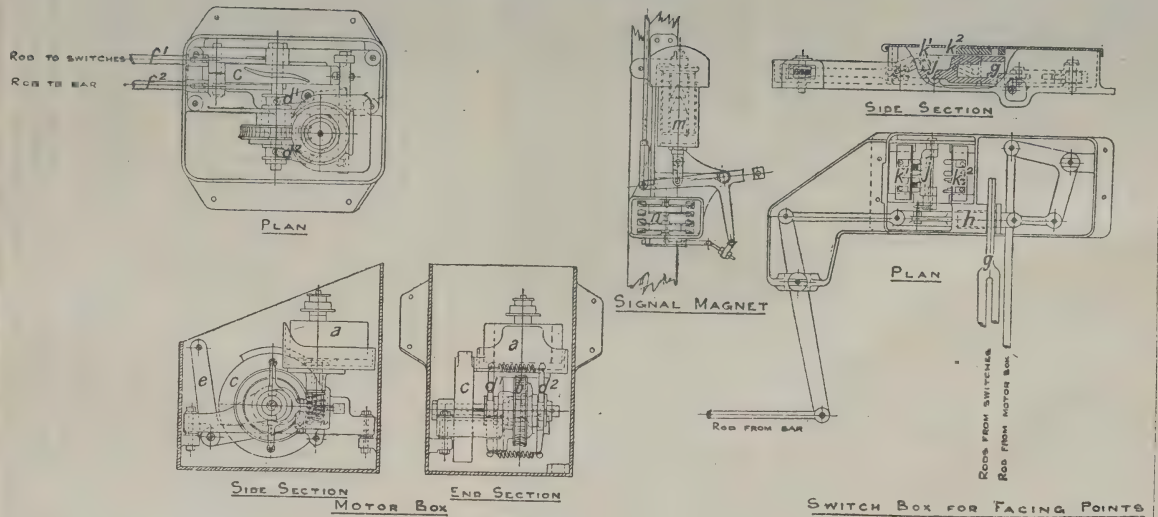

FIG. 6.

with $g\ i$ if a downward movement. This cuts off the current from the motor. But as will now be readily understood, this cannot occur until the plunger is shot and the switches held, nor can the plunger be shot unless and until the switches are in their correct position. Further detection is given by means of the contacts $l^1\ l^2$, which are in the circuits to the signals concerned. The switches for these contacts are rotated by means of short rods connected as near as practicable to the 'nose' of both point switches.

Signals in the 'Crewe' system, whether semaphore signals or the dwarf signals used in shunting operations, are changed from the 'danger' to the 'clear' position by means of a long-pull magnet m, fig. 6. A current of about 15 amperes and 100 volts is required for a fraction of a second to clear a signal, which current is then passed, by means of the switch n, through a resistance, and about 2 amperes is enough to hold the signal at 'clear.' When the lever in the signal-box is replaced partly to normal the current supply to the signal is completely cut off and the arm goes to danger by its own gravity. When the signal is fully 'on' the switch n sends the return indication and allows for the lever to complete its stroke. No return indication is necessary to show that a signal has gone from 'danger' to 'clear.' What is of importance is that it has gone from 'clear' to 'danger.'

SIEMENS SYSTEM OF ELECTRICAL SIGNALLING.

In this system any ordinary direct current supply of electrical energy having an E.M.F. of from 110 to 200 volts may be employed, the maximum current required at any one moment not usually exceeding 20 amperes per cabin worked by one man at the lower E.M.F. On alternating supplies, or where the voltage of supply is unsuitable, a small motor-generator is used; and if the supply is not always available, a battery of accumulators of about 65 cells of suitable capacity becomes necessary.

The current required for working an ordinary pair of points of the heaviest rail section (90 to 100 lbs. per yard), together with a facing point lock and bar, averages 4 amperes at 130 volts, and the time taken 2 to 3 seconds for the complete movement. The current for operating a main line signal of the heaviest type averages $1\frac{1}{2}$ ampere during the movement, lasting about $1\frac{1}{2}$ second. The motor is then automatically cut out, and the signal is held off by the coupling magnet with a current of $\frac{1}{4}$ ampere until the lever in the frame is replaced. The same holding-off current is required for the ground disc signals and route indicators, but the motors of the former take somewhat less current than those of semaphore signals. The return indication or check-lock magnets also operate with $\frac{1}{4}$ ampere.

The small amount of current required enables cables with conductors of extremely small size (No. 15 L.S.G.) to be used. The cables consist of 1, 3, 7 or more conductors insulated with impregnated paper, and lead-sheathed overall. The method of laying depends largely on local circumstances, but drawing into iron pipes or other suitable conduits, or laying in troughing (metallic or otherwise) is recommended. Drawing-in boxes are provided at suitable intervals, and in all cases near the points and signals. At these the paper cables are terminated in proper sealing boxes, and separate I.R. covered wires run through pipes to the motors, detectors, etc.

Locking Frame.

The locking frame is complete in itself, merely requiring to stand on an ordinary floor, through which only the small cables leading to the point and signal motors have to pass. The pitch of the levers is 2 ins., the height to top of same being 4 ft. from floor, whilst the width of the frame is only $12\frac{1}{2}$ ins. Its weight is only about 40 lbs. per lever. The frame can, therefore, be used in narrow cabins where space is restricted, nor does it obscure the view of the signalman when the cabin is situated above or close to the line. The frames can be built of any length without break, the standard pattern being made in panels, each having sixteen levers. The lever numbers, names and lead numbers are engraved on an inclined brass plate forming the top of the frame.

Referring to fig. 7, the source of energy is connected to the bus-bars in the locking frame marked + and −, and A is one of the fuses in each circuit, and B the reversing switch operated by the tappet C. The tappets are connected to the levers at their upper end, the mechanical locking being contained in the grooves in the boxes D, E, F, G and H, at the back of the frame.

The check-lock J also operates directly on the tappet, the object of which is to prevent the release of the interlocking between the levers concerned by delaying the completion of the stroke of the lever until such time as the return current from the apparatus worked is received in the corresponding check-lock magnet. When this has occurred, the lever is free to complete its movement. There is, therefore, no possible want of synchronism between the mechanical locking, switches, and outdoor gear.

The check-locks are operated by the check-lock magnets marked N and R for the 'Normal' and 'Reverse' positions of the lever respectively. The check-locks provided are of two types, one being with double action as used for points, in order to ensure that the points have responded to the lever in either of their positions, and the other type being of a single action for signals, as it is usual to ensure that the 'Danger' or 'Normal' position of the semaphore arm is in agreement with the lever.

When, say, a point lever is pulled, the check-lock is mechanically driven into the notch in the tappet and remains in this position until the magnet attracts its armature, and in so doing operates the check-lock so that it becomes free of the tappet and allows the full movement of

the lever to be completed. The armatures of both magnets are separate pieces and are so constructed that when the check-lock is forcibly brought into the middle or locking position by the movement of the tappet the check-lock becomes positively locked in that position and cannot be released by vibration or accidental mechanical movement. It is, therefore, impossible for the check-lock to be brought into the free position to allow of the completion of the movement of the lever except by current actually received from the points or signal.

Although the armatures of both magnets are separate pieces it is impossible, owing to their construction, for either to stick when the other is attracted.

Catch-handles are not provided on the levers, but spring bolts K working in the top-locking grooves engaging with and holding the tappets in each of their correct final positions, and also in the right positions for the check-locks to operate when the magnets receive the return current, are provided in their place.

The switches are designed to give a quick and long break, thereby avoiding sparking or tendency to arcing. They are of uniform pattern, the contact springs, L and M, only being varied,

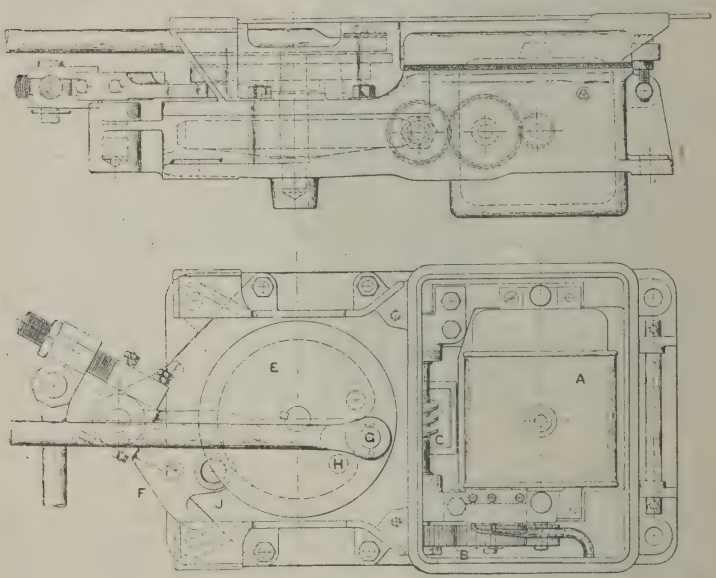

FIG. 8.

according to the work the lever performs—i.e. working a single pair of points with or without bolt or bar, two or more points, simple signal, or signal with route indicator, etc. The connecting rod O between the lever and the switch is merely an auxiliary connection, and only comes into use if the mechanical locking is disconnected for changes to be made due to alterations in the plan of the road.

In addition to the check-lock a constant indication by means of the indicator at the back of the lever is provided for points only. This intimates at all times to the signalman the state of the points, i.e. whether they are normal or reverse, or in an indefinite position. This control indicator is in series with a control magnet which operates a number of controlling contacts for the purpose of joining up or interrupting the signal circuits that require to pass through these contacts. This arrangement of detecting has the advantage that all the control contacts are brought together and can be collected and grouped for purposes of control at one common spot. It is immaterial whether these control magnets are in the cabin or not, they can be very conveniently arranged in cases under the cabin. Numbered terminals P are provided on a marble panel R to which the conductors in the cables leading to the points etc. are attached, which much simplifies the periodical testing of the latter.

The point machine, fig. 8, consists of a reversing motor A driving through toothed and worm gears B and C respectively, a friction clutch D, cam disc E, and escape crank F, coupled

by means of suitable rodding to the points. The first functions performed by the cam disc E when it begins to revolve is to unlock the points by withdrawing the plunger bolt operated by crank pin G. The escape crank F is then turned by the stud H on cam disc into a position in which the roller J on escape crank is compelled to enter into driving engagement with the cam disc, which thereupon completes the movement of the escape crank. The final movement of the cam disc holds the points in their proper position and re-locks them by re-inserting the bolt in the stretcher bar. The reverse operation occurs when the points are moved back into their original position.

The friction clutch is set to transmit power with a large margin for the heaviest points, but will slip should the points become jammed by stones etc. during movement, thus ensuring that the motor is not injured.

In order to safeguard the machine against a run through of the points in a trailing direction, the two bolts connecting the adjustable point connection to the body of the crank are so designed that they will transmit the heaviest legitimate load, but will shear under an excessive strain, such as an event mentioned above. Under such circumstances, however, the return indication current to withdraw the check-lock would not be transmitted to the cabin. Should, however,

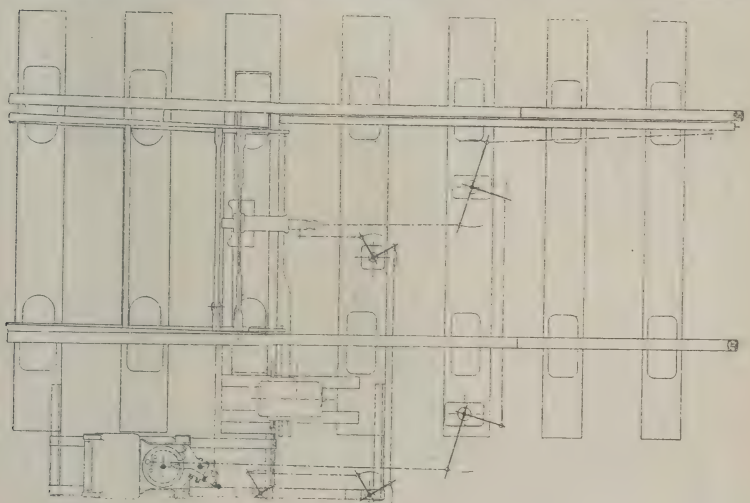

FIG. 9.

the run-through take place after the setting of the points, the return current would be broken down and an indication given in the control indicator and the signal circuit concerned would be opened.

The motors may be reversed at any part of their movement by moving the lever in the cabin to and fro between the check-lock positions.

The switching arrangements, which are carried out in the detector machine, are such that the current is not cut off from the motor until the movement of the points is completed, the momentum of the motor being then absorbed by the clutch. This slight movement of the latter at each operation ensures that the clutch is always in efficient working condition.

The worm-wheel shaft revolves on a ball-bearing at its lower end and this is kept well lubricated by the oil contained in the well of the case.

Fig. 9 shows a typical lay-out for facing point machines where the plunger bolt and locking-bar are operated from the cam shaft, which has a movement of 320°.

The detector is adapted to give a fine detection of each tongue of the points and the locking-bar. It also comprises a switch for the motor circuit in either of the complete final positions of the points and bar. The fineness of detection is secured without unduly limiting the rubbing surface.

SIGNAL OPERATING MECHANISM.

The method of operating semaphore signals is shown in fig. 10. The mechanism consists of a motor contained in a light cast-iron case attached to the back of the post. The motor revolves

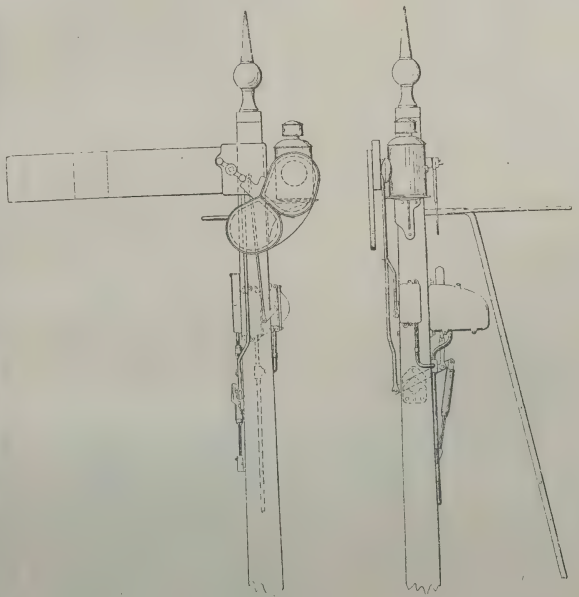

FIG. 10.—Arrangement of Mechanism for Semaphore Signal.

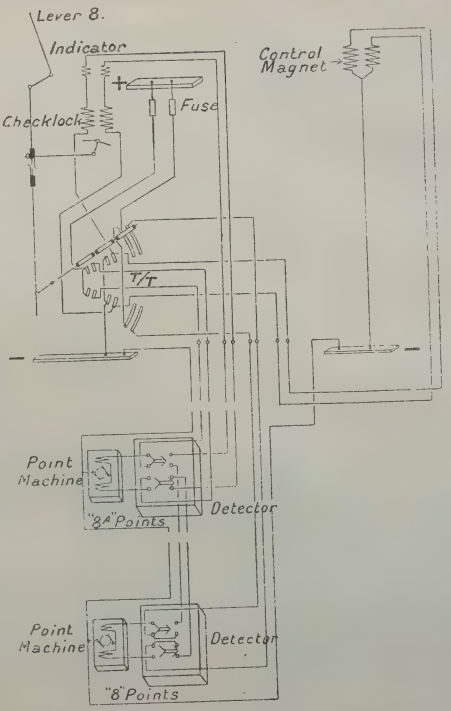

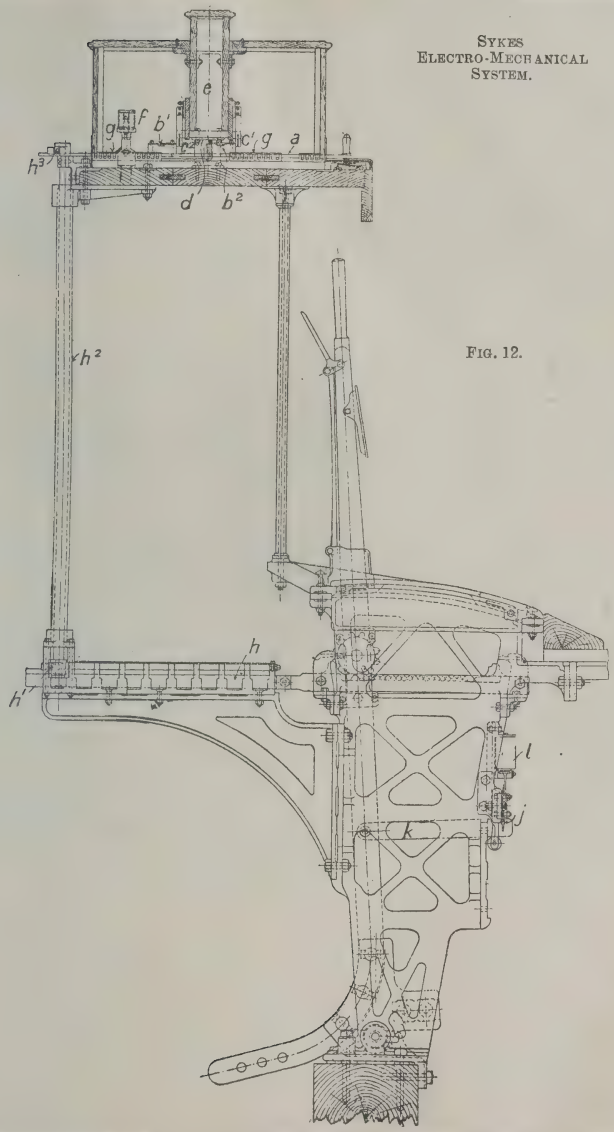

FIG. 11.—Connections for Double Points. Control System.

SYKES
ELECTRO-MECHANICAL
SYSTEM.

FIG. 12.

a coupling magnet through a worm which gears into teeth formed on the magnet casting. The armature is fixed on a shaft which has a pinion on its end and gearing with a straight rack connected to the semaphore arm. The motor revolving lowers the semaphore arm to a predetermined angle at which point its circuit is opened by a switch and the motion arrested, but the coupling magnet being still energised, the arm is held in the 'off' position until the main circuit is opened. The signal then returns to the 'danger' position by gravity, merely revolving the uncoupled shaft, all other parts remaining stationary. A safety device of simple construction, consisting of a pawl in a disc, is fitted to these machines, which effectually prevents the arm from being lowered from the 'danger' position by any other means than from the signal cabin.

A switch box attached to the signal contains a contact for giving the return indication of the signal having resumed its danger position. Contacts can also be made in the 'off' position for closing the circuit of other signals—such, for instance, as a 'distant' controlled by 'home' and 'starter.' The switch is operated by a separate light rod from the semaphore arm itself, which ensures correct indications notwithstanding any accidental disconnection of the rods between motor and arm. The switch levers making these contacts are individually adjustable, so that the semaphore arms may be lowered to any angle desired by the railway authorities and the return indication or repeater contact set to any degree of fineness.

Connections.

Fig. 11 shows the electrical connections for two points worked by one lever. Normal position. Motors working in parallel through separate fuses, check-lock, and control magnets in series through both detectors. The gear for moving signals and points has been so designed that the motors work the existing fittings, locking-bars, and plunger-bolts without any modification.

One-lever System of Railway Signalling.—Messrs. Siemens are now introducing a new system whereby each lever in the newly-designed locking frame becomes a 'Route Lever.' One lever therefore, sets up the route required irrespective of the number of points concerned, and when fully reversed lowers the signal over that route. The scheme shows a considerable saving in operative labour costs and of time in traffic movements.

SYKES ELECTRO-MECHANICAL SYSTEM.

About 2,000 levers have been installed in the electro-mechanical system of the W.R. Sykes Interlocking Signal Co., Ltd., wherein all signals are actuated by electricity, the circuits for which are completed by a small slide being drawn forward or pushed back, and all points are moved by the usual mechanical lever, elevations of which are given in fig. 12.

The slide *a* carries contact pieces b^1 b^2 which, when the slide is drawn out, put springs c^1 c^2 into contact with the plate *d*. This completes the circuit to the signal governed by the lever by means of wires passing through the box *e*. When it is necessary to control the movement of a slide, e.g., from another signal-box, or by a fouling bar or track-circuit, a pin rests normally in the slide which can only be lifted when the magnet *f* is energised. The slides are interlocked as in a mechanical frame, but on a miniature scale. The slide itself acts as its own tappet, and the locks are in the locking-boxes *g g*.

The tappet of the mechanical lever is *h*, and a stud h^1 turns the shaft h^2, and so, by a stud h^3, actuates a co-acting tappet in the electrical part. By this the mechanical levers and electrical slides are interlocked.

By an ingeniously arranged escapement wheel the movement of the mechanical tappet is only 2 ins., the same as the electrical slide. A lock *j* in the tappet *k* holds point levers when required until they are freed by the lock being lifted out of the tappet by the magnet *l* being energised.

SECTION XII

PART IV

COST OF RAILWAYS—BOARD OF TRADE REGULATIONS —RAILWAY BILLS.

COST OF RAILWAYS.

(Pre-war Prices)

General.

System of Execution involves: (1) Methods adopted for getting the stuff from cuttings and tunnels; (2) method of loading, transporting, and tipping the stuff.

Time Expended depends on the system of execution and the number of hands employed, making due allowance for bad weather and the nature of the getting and other work involved.

Cost of Permanent Way.—In a new country, where there are no strict Board of Trade Rules, few existing roads, bends, etc., to cross, and where vested interests do not prevent best route from being chosen, the cost may be taken as follows:—

A Single Line.—4 feet 8½ ins. gauge in flat country, cuttings and banks average 3 ft., rails 55 lbs., ballast 15 ins. deep (altogether of light construction), 4,500*l.* to 5,000*l.* per mile.

Heavy construction: 75-lb. rails and 24 ins. ballast, 5,800*l.* to 7,000*l.* per mile.

These prices include stations and permanent work, but not land and rolling stock.

In a hilly country the cost would, of course, be much greater.

Cost of Rolling Stock depends on kind of traffic; but 700*l.* to 1,000*l.* per mile has generally been found necessary on single lines in foreign countries.

Double Line.—The cost of making will be from 50 to 75 per cent. in excess of foregoing figures but the cost of rolling stock only from 10 to 30 per cent. more for the same traffic.

Cost in Different Countries.—In England, 40,000*l.* per mile; Scotland, 28,000*l.*; Ireland, 15,000*l.* Single-line railways in poor districts of Ireland and Scotland, 6,000*l.*; Europe, 12,000*l.* to 25,000*l.*; India, 12,000*l.* and upwards; Great Indian Peninsula, 22,000*l.*; Ceylon, 19,000*l.*; United States, 8,200*l.*; in Norway, light railways, 3 ft. 6 ins. gauge in a very difficult country, have been constructed at from 3,000*l.* to 6,000*l.*; Queensland, 6,000*l.* to 12,000*l.*

The working expenses average 40 per cent. of the gross receipts in Ireland, 45 per cent. in Scotland, and 50 per cent. in England.

In England 50 per cent. of capital (before opening) was expended in works of construction 20 in purchase of land, 10 in carrying stock, 20 in law expenses, discounts, etc.

United Kingdom Railway Expenditure and Receipts.

(Board of Trade Report.)

The following is a comparison for 1912 and 1911 of the gross amounts of the expenses of the companies under the four principal heads, these heads being those covering more particularly the expenses connected with the actual working of the lines as well as being those chiefly influenced by variations in the charges for wages, fuel, and materials :—

Head.	1912.	1911.	Increase.
	Million £.	Million £.	Million £.
Maintenance of way, works, and stations	11·70	11·75	0·05*
Locomotive power	21·84	21·06	0·78
Repairing and renewing carriages and waggons	7·16	6·98	0·18
Traffic expenses	23·46	22·51	0·95

Gross receipts of the Companies in 1912 and 1911 from passenger and goods traffic :—

—	1912.	1911.	Increase.	
	Million £.	Million £.	Million £.	Per Cent.
Receipts from Passenger Traffic	54·26	53·9	0·31	0·6
„ Goods Traffic	64·05	63·3	0·76	1·2
Total	118·31	117·2	1·07	0·9

The above statement does not include receipts from miscellaneous sources, such as steamboats, canals, docks, rents, tolls, hotels, etc.

(*Continued on page* 656.)

* Decrease.

	1912	191	316	200	40	83	830	672	626	1,298

The average cost per train mile in 1912 of locomotive power was 12·71*d.*, and of rolling stock 4·17*d.* The maintenance of way cost 6·81*d.*, and traffic expenses 13·65*d.* per train mile.

The total length of the running track of the railways of the United Kingdom at the end of 1912 was 40,034 miles, and the total length of sidings 14,875 miles.

TABLE FOR THE RAILWAYS OF THE UNITED KINGDOM, SHOWING LENGTH OF LINES, CAPITAL, PASSENGERS CONVEYED, GROSS AND NET RECEIPTS, AND WORKING EXPENSES.

Year.	Total Mileage.	Total Paid-up Capital.	Number of Passengers Conveyed, Exclusive of Season-Ticket Holders.	Receipts from Passenger Traffic.

* The Total Receipts include Rents, Tolls, Navigation, Steamboats, etc., which are not included in Traffic Receipts.

BOARD OF TRADE REGULATIONS WITH REFERENCE TO RAILWAYS.

Requirements of the Board of Trade in regard to the Opening of Railways.

(1911.)

TELEGRAPHS AND SIGNALS.

1. *Block Telegraph.*—The requisite apparatus for providing by means of the block telegraph system an adequate interval of space between following trains, and, in the case of junctions, between converging or crossing trains. In the case of single lines worked by one engine under steam (or two or more coupled together) carrying a staff, no such apparatus will be required.

2. *Signals.*—Home signals and distant-signals for each direction to be fixed at stations and junctions, with extra signals for such dock or bay lines as are used either for the arrival or for the departure of trains, and starting signals for each direction at all passenger stations which are also block posts. On passenger lines all cross-over roads and all connections for goods or minerals lines and sidings to be protected by home and distant-signals, and, as a rule, at all important running junctions a separate distant-signal to be provided in connection with each home signal. Signals may be dispensed with on single lines under the following conditions :—

(*a*) At all stations and siding connections upon a line worked by one engine only (or two engines coupled together), carrying a staff, and when all points are locked by such staff.

(*b*) At any intermediate siding connection upon a line worked under the train staff and ticket system, or under the electric staff or tablet system, where the points are locked by the staff or tablet.

(*c*) At intermediate stations, which are not staff or tablet stations, upon a line worked under the electric staff or tablet system ; sidings, if any, being locked as in (*b*).

3. The signals at junctions to be on separate posts, or on brackets ; and the signals at stations, when there is more than one arm on one side of a post, to be made to apply, the first or upper arm to the line on the left, the second arm to the line next in order from the left, and so on ; but in cases where the main or more important line is not the one on the left, separate signal posts to be provided, or the arms to be on brackets. Distant-signals to be distinguished by notches cut out of the ends of the arms, and to be controlled by home or starting signals for the same direction, when on the same post. A distant-signal arm must not be placed above a home or starting signal arm on the same post for trains going in the same direction.

In the case of sidings, a low short arm and a small signal light, distinguishable from the arms or lights for the passenger lines, may be employed, but in such cases disc signals are, as a rule, preferable.

Every signal arm to be so weighted as to fly to and remain at danger on the breaking at any point of the connection between the arm and the lever working it.

4. The signal lights to be green for all right, and red for danger ; the back lights (visible only when the signals are at danger) to be white.

POINTS AND JUNCTIONS.

5. *Points.*—Facing points to be placed as near as practicable to the levers by which they are worked or bolted. The limit of distance from levers working points to be 200 yards* in the case of facing points and 300 yards in the case of trailing points on the main line, or safety points of goods lines and sidings.

In order to ensure that the points are in their proper position before the signals are lowered, and to prevent the signalman from shifting them while a train is passing over them, all facing points must be fitted with facing point blocks and locking bars, and with means for detecting any failure in the connections between the signal box and points. The length of the locking bars to exceed the greatest wheel-base between any two pairs of wheels of the vehicles in use on the line, and the stock rails to be tied to gauge with iron or steel ties. All points, whether facing or trailing, to be worked or bolted by rods, and not by wires, and to be fitted with two connecting rods.

6. *Interlocking.*—The levers by which points and signals are worked to be interlocked and, as a rule, brought close together, into the position most convenient for the person working them, in a signal box, or on a properly constructed stage. The signal box to be commodious, and to be supplied with a clock and with a separate block instrument for signalling trains on each line of rails. The point levers and signal levers to be so placed in the box that the signalman when working them shall have the best possible view of the railway, and the box itself to be so situated as to enable the signalman to see the arms and the lights of the signals and the working of the points. The back lights of the signal lamps to be made as small as possible, having regard to efficiency, and when the front lights are visible to the signalman in his box no back lights to be provided. The fixed lights in the signal box to be screened off, so as not to be mistakable for the signals exhibited to control the running of trains. If, from any unavoidable cause, the arm and light of any signal cannot be seen by the signalman, they must, as a rule, be repeated in the box.

7. The interlocking to be so arranged that the signalman shall be unable to lower a signal for the approach of a train until after he has set the points in the proper position for it to pass; that it shall not be possible for him to exhibit at the same moment any two signals that can lead to a collision between two trains; and that after having lowered the signals to allow a train to pass he shall not be able to move any points connected with or leading to the line on which the train is moving. Points also, if possible, to be so interlocked as to avoid the risk of a collision. Home or starting signals next in advance of trailing points, when lowered, to lock such points in either position, unless such locking will unduly interfere with the traffic. A distant-signal must not be capable of being lowered unless the home and starting signals in advance of it have been lowered.

8. *Sidings.*—Sidings to be so arranged that shunting operations upon them shall cause the least possible obstruction to the passenger lines. Safety points to be provided upon goods and mineral lines and sidings, at their junctions with passenger lines, with the points closed against the passenger lines and interlocked with the signals.

9. *Junctions.*—Junctions, siding connections, and cross-over roads in a passenger station, to be so arranged as to prevent, as far as possible, any necessity for standing trains on them.

10. The junctions of single lines to be, as a rule, formed as double-line junctions.

STATIONS.

11. *Stations.*—The lines of railway leading to the passenger platforms to be arranged so that the engines shall always be in front of the passenger trains as they arrive at and depart from a station; and so that in the case of double lines, or of passing places on single lines, each line shall have its own platform. At terminal stations a double line of railway must not, as a rule, end as a single line.

12. Platforms to be continuous and of sufficient length to accommodate the longest trains using them; to be not less than 6 feet wide for stations of small traffic, nor less than 12 ft. wide for important stations; the descents at the ends of platforms to be by ramps, and not by steps. Pillars for the support of roofs and other fixed works not to be less than 6 ft. from the edges of the platforms. The height of the platforms above rail level to be 3 ft., save under exceptional circumstances, and in no case less than 2 ft. 6 ins. The edges of the platforms to overhang not less than 12 ins. As little space as possible to be left between the edges of the platforms and those of the footboards on the carriages. Shelters and conveniences to be provided on platforms where necessary. Names of stations to be shown on boards and on the platform lamps.

13. When stations are placed on or near a viaduct or bridge under the railway, a parapet or fence on each side to be provided of sufficient height to prevent passengers, who may by mistake leave the carriages when not at the platform, from falling from the viaduct or bridge in the dark.

---

* In cases where facing points are 'power worked' this distance has been provisionally extended to 300 yards. 250 yards now allowed on condition that in addition to the detection of switch blades the position of the bolt lock is also efficiently detected.

14. Foot-bridges or subways to be provided for passengers to cross the railway at all exchange and other important stations. Staircases or ramps leading to or from platforms to be at no point narrower than at the top, and the available width to be in no case contracted by any erection or fixed obstruction whatever below the top.

At all stations where crowding may be expected the staircases or ramps to be of ample width, and barriers for regulating the entrance of the crowd at the top to be erected. If in such cases there are gates at the bottom, a speaking-tube or other means of communication between the top and bottom to be provided; and in all cases gates at the bottom of a staircase or ramp to open outwards. For closing the openings at the top, sliding-bars or gates are considered best. The steps of staircases to be never less than 11 ins. in the tread, nor more than 7 ins. in the rise, and midway landings to be provided where the height exceeds 10 ft.

Efficient handrails to be provided on both staircases and ramps. Where ramps are used the inclination not to exceed 1 in 8.

15. A clock to be provided at every station, in some conspicuous position visible from the platform.

16. *Stations or sidings on gradients.*—No station to be constructed, and no siding to join a passenger line, on a steeper gradient than 1 in 260, except where it is unavoidable. When the line is double, and the gradient at a station or siding junction is necessarily steeper than 1 in 260, and when danger is to be apprehended from vehicles running back, a catch-siding with points weighted for the siding, or a throw-off switch, to be provided to intercept runaway vehicles, at a distance, outside the home signal for the ascending line, greater than the length of the longest train running upon the line.

Under similar circumstances, when the line is single, provision for averting danger from runaway vehicles to be made :—

1. At a station in one of the following manners :—

   a. A second line to be laid down, a second platform to be constructed, and a catch-siding or throw-off switch to be provided on the ascending line inside the loop points.

   b. A loop line to be constructed lower down the incline than the station platform with a similarly placed catch-siding or throw-off switch.

2. At a siding junction, in one of the following manners—except where it is possible to work the traffic with the engine at the lower end of a goods or mineral train, in which case an undertaking (see No. 34) to do so, given by the company, will be accepted as sufficient :—

   a. A similar loop to be constructed, as in the case of a station.

   b. Means to be provided for placing the whole train on sidings clear of the main line before any shunting operations are commenced.

Turntables.

17. *Turntables.*—Engine turntables of sufficient diameter to enable the longest engines and tenders in use on the line to be turned without being uncoupled to be erected at terminal stations, and at junctions and other places at which the engines require to be turned, except in cases of lines upon which the traffic is worked by tank engines fitted for running in both directions. All turntables to be kept at safe distances from the adjacent lines of rails.

Bridges and Viaducts.

18. *Bridges and Viaducts.*—Cast iron must not be used for railway under-bridges except in the form of arch-ribbed girders, where the material is in compression.

In a cast-iron arched bridge, or in the cast-iron girders of an over-bridge, the breaking weight of the girders not to be less than three times the permanent load due to the weight of the superstructure, added to six times the greatest moving load that can be brought upon it.

In a wrought-iron or steel bridge the greatest load which can be brought upon it, added to the weight of the superstructure, not to produce a greater strain per square inch on any part of the material than five tons where wrought iron is used, or six tons and a half where steel is used.

The engineer responsible for any steel structure to forward to the Board of Trade a statement of the tests to which the material has been subjected. (See Appendix I., page 662.)

19. In cases where bridges or viaducts are constructed wholly or partially of timber, a sufficient factor of safety to be provided for.

N.B.—The heaviest engines, boiler-trucks, or travelling-cranes in use on railways afford a measure of the greatest moving loads to which a bridge can be subjected. The above rules apply equally to the main and transverse girders and rail bearers.

20. It is desirable that viaducts should, as far as possible, be wholly constructed of brick or

stone, and in such cases they must have parapet walls on each side not under 4 ft. 6 ins. in height above the rail level and at least 18 ins. thick up to a height of 12 ins. above rail level.

Where it is not practicable to construct the viaducts of brick or stone, and iron or steel girders are made use of, it is considered best that in important viaducts the permanent way should be laid between the main girders. In all cases a substantial railing or parapet with a height of not less than 4 ft. 6 ins. above rail level must be provided by an addition to the girders, unless the girders themselves are sufficiently high, and in exposed places, where necessary, an efficient wind screen may be required. On important viaducts where the superstructure is of iron, steel, or timber, substantial outside wheel-guards to be fixed, above the level of and as close to the outer rails as possible, but not so as to be liable to be struck by any part of an engine or train running on the rails.

In the construction of the abutments or piers which support the girders of high bridges and viaducts cast-iron columns of small size must not be used. In all large structures a wind pressure of 56 lbs. per square foot to be assumed for the purpose of calculation, which will be based on the rules laid down in the report dated May 20, 1881, of the Committee appointed by the Board of Trade to consider the question of wind pressure on railway structures. (See Appendix II., p. 662.)

21. The upper surfaces of the wooden platforms of bridges and viaducts to be protected from fire.

PERMANENT WAY.

22. *Permanent way.*—The joints of rails to be secured by means of fishplates, or by some other equally secure fastening. On main lines and lines where heavy traffic may be worked at high speed the chairs not to weigh less than 45 lbs., but on branch lines or lines on which the traffic is light and the speed is low, chairs weighing not less than 30 lbs. may be used.

23. When chairs are used to support the rails they must be secured to the sleepers, at least partially, by iron spikes or bolts. With flat-bottomed rails, when there are no chairs, or with bridge rails, the fastenings at the joints, and at some intermediate places, to consist of fang or other through-bolts; and such rails, on curves with radii of 15 chains or less, to be tied to gauge by iron or steel ties at suitable intervals.

24. In any curve where the radius is 10 chains or less, a check rail to be provided.

25. Diamond crossings, as a rule, not to be flatter than 1 in 8.

26. *Width of line.*—No standing work (other than a passenger platform) to be nearer to the side of the widest carriage in use on the line than 2 ft. 4 ins., at any point between the level of 3 ft. above the rails and the level of the upper parts of the highest carriage doors. This applies to all arches, abutments, piers, supports, girders, tunnels, bridges, roofs, walls, posts, tanks, signals, fences, and other works, and to all projections at the side of a railway, constructed to any gauge.

27. *Intervals between lines.*—The intervals between adjacent lines of rails where there are two lines only not to be less than 6 ft. Where additional running lines of rails are alongside the main lines, an interval of not less than 10 ft. to be provided, if possible, between such additional lines and the main lines. The interval between running lines and sidings to be not less than 8 ft.

28. *Level crossings.*—At all level crossings of public roads the gates to be so constructed that they may be closed either across the railway or across the road at each side of the crossing, and a lodge, or in the case of a station a gate-keeper's box, to be provided, unless the gates are worked from a signal box. The gates must not be capable of being opened at the same time for the road and the railway, and must be so hung as not to admit of being opened outwards towards the road. Stops to be provided to keep the gates in position across the road or railway. Wooden gates are considered preferable to iron gates and single gates on each side to double gates. Red discs or targets must be fixed on the gates, with lamps for night use; or semaphore signals in one or both directions interlocked with the gates may be required. Fixed signals will be necessary with double gates. At all level crossings of public roads or footpaths a foot-bridge or a subway may be required.

At occupation and field crossings the gates must be hung so as to open outwards from the line.

29. Sidings connected with the main lines near a public road level crossing to be so placed that shunting may be carried on with as little interference as possible with the level crossing, and, as a rule, the points of the siding to be not less than 100 yards from the crossing.

30. At public road level crossings in or near populous places the lower portions of the gates to be either close barred or covered with wire netting.

31. *Mile posts, etc.*—Mile posts, half-mile and quarter-mile posts, and gradient-boards to be provided along the line.

32. *Platelayers' refuges, etc.*—Tunnels and long viaducts to be in all cases constructed with

refuges for the safety of platelayers. On under-bridges without parapets, handrails to be provided. Viaducts of steel, iron, or timber to be provided with manholes or other facilities for inspection.

BRAKES.

33. *Continuous brakes.*—Continuous brakes (in accordance with the Regulations of Railways Act of 1889) complying with the following requirements to be provided on all trains carrying passengers, viz. :—

(1) The brake must be instantaneous in action, and capable of being applied by the engine-driver and guards.

(2) The brake must be self-applying in the event of any failure in the continuity of its action ;

(3) The brake must be capable of being applied to every vehicle of the train, whether carrying passengers or not ;

(4) The brake must be in regular use in daily working ;

(5) The materials of the brake must be of a durable character, and easily maintained and kept in order.

UNDERTAKINGS.

34. Any undertaking furnished by a railway company to be under the seal and signed by the Chairman and Secretary of the Company.

MODES OF WORKING SINGLE LINES.

In the case of a line being single, an undertaking must be sent to the Board of Trade, through the Inspecting Officer, to the effect that one of the three following modes of working single lines will be adopted, namely :—

I. By train-staff and train tickets in the mode described in the following rules, combined with the absolute block-telegraph system :

Rules for working the single line between A, B, C, etc.

1. Either a train-staff or a train ticket is to be carried with each engine or train to and fro, and for this purpose (one, two, or more) train-staffs and sets of train-tickets will be employed, e.g. :—

Number of Staffs.	Colour of Staff and Ticket.	Form of Staff and Ticket.
One between A and B	Red	Square
One between B and C, etc. . . .	Blue, etc.	Round, etc.

2. No engine or train is to be permitted to leave or pass either of the staff stations, A, B, C, etc., unless the staff for the portion of the line over which it is to travel is then at the station ; and no engine-driver is on any account to leave or pass a staff-station without seeing such train-staff.

3. If no second engine or train is intended to follow, the staff is to be given to the engine-driver.

4. If other engines or trains are intended to follow before the staff can be returned, a train-ticket, stating 'staff following,' is to be given to the engine-driver of the first engine, and so on with any other except the last, the staff itself being sent with the last. After the staff has been sent away, no other engine or train is to leave the staff-station under any circumstances whatever until the return of the staff.

5. The train-tickets are to be kept in a box fastened by an inside spring, and the key to open the box must be the train-staff, so that a ticket cannot be obtained without the train-staff. The removal of the train-staff must lock the box.

6. The train-staffs, the train-tickets, and the ticket-boxes are to be painted or printed in different colours, e.g., red for the line between A and B, blue for that between B and C, etc. ; the inside springs and the keys on the staffs being so arranged that the red staff cannot open the blue box, or the blue staff the red box, and so forth.

7. The ticket-boxes are to be kept in the signal boxes or in the booking-offices at the staff-stations.

8. The sole person authorised to receive, exhibit, or deliver the staff or ticket is either the station-master, the inspector, the signalman, or the person in charge for the time at a staff-station.

9. The usual special train tail-signal, 'engine or train following,' must be used by every engine or train carrying a ticket, for the information of the platelayers, gatekeepers, and others.

10. When a ballast train has to do work on the line, the staff only and no tickets to be used by such train. This will close the line whilst the ballast train is at work. The ballast train must proceed to one of the two staff-stations in order to open the line before the ordinary traffic can be resumed.

11. In the event of an engine or train breaking down between two staff-stations, the fireman or guard is to take the train-staff, if with the train, to the staff-station in the direction whence assistance may be expected, so that the staff may be at that station on the arrival of an engine. Should the engine or train that fails be in possession of a train-ticket instead of the staff, assistance can only come from the station at which the train-staff has been left. The fireman will accompany any assisting engine to the place where the engine or train broke down.

II. With only one engine in steam, or two or more engines coupled together, upon the single line or any section thereof at one and the same time.

Such engine or engines to carry the staff belonging to the line or section on which the train is travelling.

(N.B.—No tickets to be allowed under this mode of working.)

III. By the electric tablet or electric staff system, under which only one of the tablets (or staffs) applying to any section can be in use at the same time.

(N.B.—The approval of the Board of Trade to be obtained for the apparatus proposed to be used, and for the rules of working, which should be of a somewhat similar character to those detailed under mode of working No. 1.)

Board of Trade (Railway Department).

HERBERT JEKYLL.

Appendix I.

Use of Steel in Railway Structures.

Extract from the Report of the Committee appointed by the Board of Trade to consider the Practicability of assigning a safe Coefficient for the use of Steel in Railway Structures.

'We recommend that the employment of steel in engineering structures should be authorised by the Board of Trade under the following conditions, namely :—

'1st. That the steel employed should be cast steel or steel made by some process of fusion, subsequently rolled or hammered, and that it should be of a quality possessing considerable toughness and ductility, and that a certificate to the effect that the steel is of this description and quality should be forwarded to the Board of Trade by the engineer responsible for the structure.

'2nd. That the greatest load which can be brought upon the bridge or structure, added to the weight of the superstructure, should not produce a greater strain in any part than 6½ tons per square inch.'

Appendix II.

Wind Pressure on Railway Structures.

Extract from the Report of the Committee appointed by the Board of Trade to consider the Question of Wind Pressure on Railway Structures.

'We are of opinion that the following rules will sufficiently meet the cases referred to :—

'(1) That for railway bridges and viaducts a maximum wind pressure of 56 lbs. per square foot should be assumed for the purpose of calculation.

'(2) That where the bridge or viaduct is formed of close girders, and the tops of such girders are as high or higher than the top of a train passing over the bridge, the total wind pressure upon such bridge or viaduct should be ascertained by applying the full pressure of 56 lbs. per square foot to the entire vertical surface of one main girder only. But if the top of a train passing over the bridge is higher than the tops of the main girders, the total wind pressure upon such bridge or viaduct should be ascertained by applying the full pressure of 56 lbs. per square foot to the entire vertical surface from the bottom of the main girders to the top of the train passing over the bridge.

'(3) That where the bridge or viaduct is of the lattice form or of open construction, the wind pressure upon the outer or windward girder should be ascertained by applying the full pressure of 56 lbs. per square foot, as if the girder were a close girder, from the level of the rails to the top of a train passing over such bridge or viaduct, and by applying in addition the full pressure of 56 lbs. per square foot to the ascertained vertical area of surface of the ironwork of the same girder situated below the level of the rails or above the top of a train passing over such bridge or viaduct. The wind pressure upon the inner or leeward girder or girders should be

ascertained by applying a pressure per square foot to the ascertained vertical area of surface of the ironwork of one girder only situated below the level of the rails or above the top of a train passing over the said bridge or viaduct, according to the following scale, viz. :—

'(*a*) If the surface area of the open spaces does not exceed two-thirds of the whole area included within the outline of the girder, the pressure should be taken at 28 lbs. per square foot.

(*b*) If the surface area of the open spaces lies between two-thirds and three-fourths of the whole area included within the outline of the girder, the pressure should be taken at 42 lbs. per square foot.

'(*c*) If the surface area of the open spaces be greater than three-fourths of the whole area included within the outline of the girder, the pressure should be taken at the full pressure of 56 lbs. per square foot.

'(4) That the pressure upon arches and the piers of bridges and viaducts should be ascertained as nearly as possible in conformity with the rules above stated.

'(5) That in order to ensure a proper margin of safety for bridges and viaducts in respect of the strains caused by wind pressure, they should be made of sufficient strength to withstand a strain of four times the amount due to the pressure calculated by the foregoing rules. And that, for cases where the tendency of the wind to overturn structures is counteracted by gravity alone, a factor of safety of 2 will be sufficient.'

STANDING ORDERS OF THE HOUSE OF COMMONS WITH REFERENCE TO RAILWAY BILLS.

The following are the principal Orders relating directly to railways.

Estimate.

37. The estimate for any works proposed to be authorised by any railway, tramway, tramroad, subway, canal, dock, or harbour Bill shall be in the following form, or as near thereto as circumstances may permit :—

ESTIMATE of the proposed (Railway).

Line, No. .									Whether Single or Double.	
Length of line				*Miles.*	*Fgs.*	*Chs.*				
Earthworks :		*Cubic Yds.*		*Price per Yd.*			£	*s.*	*d.*	£ *s.* *d.*
Cuttings—Rock

Metallings of roads and level crossings										
Gatekeepers' houses at level crossings										
Permanent way, including fencing :										
	Miles.	*Fgs.*	*Chs.*	at	*Cost per Mile.* £	*s.*	*d.*			
Permanent way for sidings, and cost of junctions										
Stations										
Contingencies									per cent.	
Land and buildings :										
	A.	R.	P.							
							TOTAL		£	

The same details for each branch, and general summary of total cost.

Plans.

42. In all cases where it is proposed to make, vary, extend, or enlarge any railway, the plan shall exhibit thereon the distances in miles and furlongs from one of the termini; and a memorandum of the radius of every curve not exceeding one mile in length shall be noted on the plan in furlongs and chains; and where tunnelling as a substitute for open cutting is intended, the same shall be marked by a dotted line on the plan, and no work shall be shown as tunnelling in the making of which it will be necessary to cut through or remove the surface soil.

43. If it be intended to divert, widen, or narrow any public carriage-road, navigable river, canal, or railway, the course of such diversion and the extent of such widening or narrowing shall be marked upon the plan; and if it be intended to divert any public foot-path, the course of such diversion shall be marked upon the plan.

44. When a railway is intended to form a junction with an existing or authorised line of railway, the course of such existing or authorised line of railway shall be shown on the deposited plan for a distance of 800 yards on either side of the proposed junction, on the same scale as the scale of the general plan.

Sections.

47. The section shall be drawn to the same horizontal scale as the plan, and to a vertical scale of not less than one inch to every one hundred feet, and shall show the surface of the ground marked on the plan, the intended level of the proposed work, the height of every embankment and the depth of every cutting, and a datum horizontal line, which shall be the same throughout the whole length of the work, or any branch thereof respectively, and shall be referred to some fixed point (stated in writing on the section), near some portion of such work, and in the case of a canal, cut, navigation, public carriage-road or railway, near either of the termini, the distance of such fixed point above or below an ordnance bench mark in the locality of the proposed works, and near one of the termini, and the height of such bench mark above ordnance datum shall also be stated.

48. In cases of Bills for improving the navigation of any river, there shall be a section which shall specify the levels of both banks of such river; and where any alteration is intended to be made therein, it shall describe the same by feet and inches, or decimal parts of a foot.

49. In every section of a railway the line of the railway marked thereon shall correspond with the upper surface of the rails.

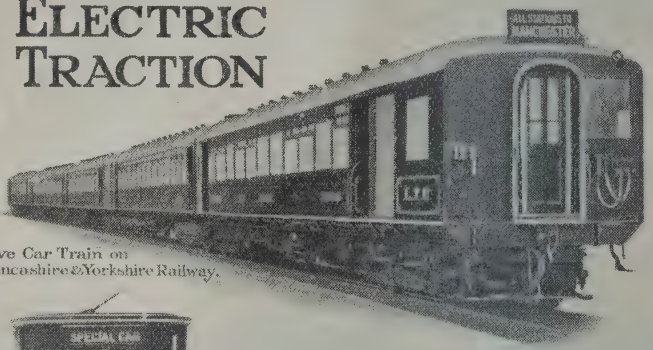
50. Distances on the datum line shall be marked in miles and furlongs, to correspond with those on the plan; a vertical measure from the datum line to the line of the railway shall be marked in feet and inches, or decimal parts of a foot, at the commencement and termination of the railway, and at each change of the gradient or inclination thereof; and the proportion or rate of inclination between every two consecutive vertical measures shall also be marked.

51. Wherever the line of the railway is intended to cross any public carriage-road, navigable river, canal, or railway, the height of the railway over or depth under the surface thereof and the height and span of every arch of all bridges and viaducts by which the railway will be carried over the same, shall be marked in figures at every crossing thereof; and where the railway will be carried across any such public carriage-road or railway, on the level thereof, such crossing shall be so described on the section; and it shall also be stated if such level will be unaltered.

52. If any alteration be intended in the water level of any canal, or in the level or rate of inclination of any public carriage-road or railway which will be crossed by the line of railway, then the same shall be stated on the section, and each alteration shall be numbered; and cross-sections, in reference to the numbers, on a horizontal scale of not less than one inch to every three hundred and thirty feet, and on a vertical scale of not less than one inch to every forty feet, shall be added, which shall show the present surface of such road, canal, or railway, and the intended surface thereof when altered; and the greatest of the present and intended rates of inclination of the portion of such road or railway intended to be altered shall also be marked in figures thereon; and where any public carriage-road is crossed on the level a cross-section of such road shall also be added, and all such cross-sections shall extend for two hundred yards on each side of the centre line of the railway.

53. Wherever the extreme height of any embankment, or the extreme depth of any cutting, shall exceed five feet, the extreme height over or depth under the surface of the ground shall be marked in figures upon the section; and if any bridge or viaduct of more than three arches shall intervene in any embankment, or if any tunnel shall intervene in any cutting, the extreme height or depth shall be marked in figures on each of the parts into which such embankment or cutting shall be divided by such bridge, viaduct, or tunnel.

54. Where tunnelling as a substitute for open cutting, or a viaduct as a substitute for solid embankment, is intended, the same shall be marked on the section, and no work shall be shown as tunnelling in the making of which it will be necessary to cut through or remove the surface soil.



55. When a railway is intended to form a junction with an existing or authorised line of railway, the gradient of such existing or authorised line of railway shall be shown on the deposited section, and in connection therewith, and on the same scale as the general section, for a distance of 800 yards, on each side of the point of junction.

ELECTRIC TRACTION.

The technical arrangements in electric tramways are practically standardised all over the world. Two four-pole totally enclosed series motors are used either with or without interpoles. The nominal rating of each motor is 30 to 40 h.p. with double-deck cars. The transmission of current is done by means of an overhead trolley wire and return through the rails, the current supplied to the car by means of a wheel trolley or bow collector. The voltage is 500 to 600; a few American interurban tramways have, however, adopted a pressure of 1,200 volts. A drum controller is used, which allows of series-parallel control. Braking is done either by means of an air brake or an electric brake, the motor acting as a generator and sending current into a magnetic rail brake, hand brakes serving as a spare. Only for short railways has it been possible to generate all the current as 600 volts direct current in the power station. For longer lines, it is standard practice to generate in the power station high tension three-phase current, and to convert it in sub-stations into direct current. The motor generator used before for this purpose has been replaced in most cases by the rotary converter, which has higher efficiency and overload capacity, or by the motor-converter. The mercury-vapour rectifier is also coming into use (see Section XXXII., Electrical Engineering).

Direct current of 600 volts has been used also for heavy traction. It is then usual to replace the hand controller by the multiple unit control, which consists of small master controllers and a number of switches similar to circuit breakers, which are connected to the motors and tappings of the resistance grids. The overhead trolley wire is often replaced, for heavy traction, by a third rail. In England, where the Board of Trade regulations require a very small voltage drop in the earth return, it has in some cases been necessary to add an insulated fourth rail in order to obviate the drop in the rails, which elsewhere serve as return circuit. With this system, problems of the heaviest traction have been satisfactorily solved. For instance, the locomotive of the Pennsylvania Railway has two multipolar motors of 1,000 h.p. each fixed inside the cab to haul very heavy trains. The maximum output of this locomotive is nearly 4,000 h.p. Some well-known examples of the 600-volt D.C. system in England are the Liverpool Overhead Railway, L. & Y. Railway, London Underground, and the North Eastern Railway (Tyneside lines).

For main lines with infrequent train service, the efficiency of the sub-stations is comparatively low, and the running costs are very high, because the sub-stations have to deal with the very heavy peak and have a poor load factor. Also the number of sub-stations must be great, and the transmission losses in the third rail are heavy.

The most popular motor for A.C. traction is the single-phase series motor, which has similar characteristics to the series D.C. motor, i.e., a torque increasing with reduced speed. It has a compensating winding in order to counteract the armature reaction. In these motors it is not possible to use on the commutator such high voltage as in direct-current motors with satisfactory commutation, and they work, as a rule, with a voltage of 200 to 300, and have, therefore, more brushes and a bigger commutator than a D.C. motor of the same output. On the trolley line, however, a much higher voltage, for instance 11,000 volts, can be used, which is stepped down by means of a stationary transformer inside the locomotive to the lower voltage required. In starting, the A.C. system has an advantage in that no resistances are required, and the speed of the motor can be regulated by switching it on to different tappings on the transformer. The control arrangements with master controller and switches are similar to those described with heavy D.C. traction, with the exception that here no resistance grids are required. The periodicity used for single-phase traction is, as a rule, 15 or 25, motors of the same output being lighter for the lower frequency. Other types of motors used for A.C. railways are the plain repulsion motor (the regulation being effected by means of brush shifting), and the repulsion series motor.

Three-phase traction has been used to a large extent in Italy and Switzerland, and, in the beginning of the century, on the experimental Berlin-Zossen line, where speeds of 130 miles per hour were obtained. The main disadvantage of the three-phase system is the necessity of at least two overhead wires. The three-phase induction motors used have a considerably lower weight, and at full speed a better efficiency than single-phase commutator motors. The absence of a commutator is also a great advantage. On the other hand, there is only one, or if the cascade system is used, only two economical speeds. The starting and speed reduction must be obtained by means of resistances (liquid controllers) in the rotor circuit. Speeding up above the normal speed can only be obtained to a certain extent on a slope, by running downhill with the motor power shut off. Running downhill with the motor connected to the line keeps the speed very near to synchronous speed, and allows of recuperating the energy previously expended in climbing uphill by sending power back into the line, a feature which is not possible either with the D.C. or single-phase system as usually applied.

Recently high-tension direct current has been used for electric traction. In America the voltage is doubled by using two rotary converters in series in the sub-stations, with two motors in series on the car, thus keeping the standard apparatus with the exception of the better insulation required. The multiple unit control is used. In order to keep the advantages of the series parallel control, it is necessary to use on a car two groups of two motors, *i.e.* four motors. On the Continent several small 1,000-volt lines have been built, with motors wound for the full voltage. For high voltage D.C. railways as a rule an overhead trolley wire with catenary suspension is used. (*Rosenberg.*)

ELECTRIC RAILWAYS.

The most extensive electrification of a steam railway in the world is that of the Chicago, Milwaukee and St. Paul Railway, U.S.A. Trains of 3,000 tons have been hauled on this railway by electric locomotives, and the regenerative system of control is employed with success. Power is transmitted at 100,000 volts, three-phase, converted to direct current at 3,000 volts, and distributed by a catenary overhead construction. The system has been in operation for six years, and has proved completely successful. Gearless locomotives are used with 12 driving and 2 guiding axles, the motor armatures being mounted direct on the axles. The continuous tractive effort is 42,300 lbs. The motors are connected three in series at full speed. This is the first application of gearless locomotives on mountain service with gradients up to 2 per cent. The geared locomotives have 6 twin motors, giving a continuous capacity of 3,200 h.p. and a tractive effort of 49,000 lbs. at 24·5 miles per hour, the maximum starting effort being 110,000 lbs. The electrically operated portion of the railway is 440 miles long, with heavy gradients, including one of 2 per cent. for 21 miles, over which trains of 3,000 tons have been hauled.

The gearless locomotives for passenger service weigh 521,200 lbs., the load on each driving axle being 38,140 lbs. The maximum power at one-hour rating is 3,480 h.p., and the total tractive effort is 46,000 lbs. at 27·5 m.p.h.

Control is effected on the series-parallel system, the combinations ranging from twelve motors in series to three in series and four sets in parallel. Regeneration is effected by using some of the motors for exciting the fields of the others, the latter acting as generators and returning energy to the line. A new section 217 miles long has been electrified. An important engineering commission advising the French Government on the electrification of 7,800 kilometres of railway in France, after visiting the United States, reported that the energy consumption on this line was 27 watt-hours per ton-kilometre, and recommended the D.C. system at 3,000 volts as 'the only system suitable for the electrification of heavy traction lines.'

The Manchester-Bury section of the L. & Y. Railway, comprising 22 miles of single track, is operated by direct current at 1,200 volts, with a third rail, and the Shildon-Newport branch of the North-Eastern Railway, 19 miles long, dealing with heavy mineral traffic, is operated at 1,500 volts with overhead contact wires. The N.E. Railway Company is contemplating the adoption of a large scheme of main-line electrification.

On the Butte, Anaconda and Pacific Railway, operated with direct current at 2,400 volts, the average train-load going west is 4,456 tons, on an average gradient of 0·3 per cent. (maximum 0·6). The speed of the loaded trains is up to 15 miles per hour for freight, and 55 miles per hour for passenger traffic. Three electricians maintain 28 locomotives and three tractor trucks, the car heating, and the power, heating and lighting services of the workshops, and the mechanical staff is less than half as large as with steam operation. Tyres last 45,000 miles ; motor brushes 18,000 miles ; contact tubes 50,000 miles. Maintenance costs are 19*d.* per locomotive mile.

On the Lake Erie and Northern Railway a steel-reinforced aluminium bearer cable is employed, consisting of seven strands of steel wire and 54 of aluminium, all 0·1118 in. in diameter. The contact wire consists of a No. 0000 galvanised steel wire, having a conductivity 14 per cent. of that of copper. The bearer cable has a sag of 2 ft. at 60° F. The line is operated at 1,500 volts, and regenerative control is used from 26 to 7 miles per hour, a range covering 93 per cent. of the kinetic energy.

Fig. 1, page 670, shows the type of construction of the permanent way and conductor rails used on most of the London Tube Railways. There are two conductor rails, the outer being the positive, and the inner the negative, rail. The insulators are of brown stoneware.

Conductor Rail Leakage.

Tests on the down road of the Baker Street and Waterloo Railway gave the following results :—

Length of track tested, miles	3·47
Volts between positive and negative	575
Volts between outer rail and earth	520
Volts between centre rail and earth	55
Leakage, positive to negative, amperes	0·68
Leakage per mile of single track	0·196
Leakage, outer rail earthed, amperes	6·75
Leakage, centre rail earthed, amperes	0·74

(*Fortenbaugh, Proc. Am. Inst. E.E.*)

Experiments made by the U.S. Bureau of Standards show that tramway tracks laid on concrete have a low resistance to earth—from 0·2 to 0·5 ohm per 1,000 feet of single track. With crushed stone ballast under a concrete roadbed the resistance is about three times as great, and on crushed stone ballast with 'Tarvia' finish the resistance is 2 to 3 ohms. Track laid on wooden sleepers embedded in earth has a resistance of 1 to 1·5 ohms. Open track on sleepers laid on good stone ballast has a resistance of 10 to 15 ohms or more in dry weather, 3 to 5 in wet weather, per 1,000 ft. of single track. Chemical salts used to preserve the sleepers greatly reduce the resistance.

Main Line Electric Traction.

The electrification of main lines of railway has become a subject of immediate interest. The greatest progress in this direction has taken place in the United States, where 675 electric locomotives are running on 4,875 miles of route, while the total in all other countries amounts to 450 locomotives on 1,000 miles of route. Operating results show a saving of 70 per cent. of the coal required for steam haulage. United States practice favours the use of motors geared to the axles, or gearless motors mounted directly on the axles ; European practice tends towards the use of side rods driven from the motors by cranks. The usual method of collecting the current is by means of pantographs carrying sliders which rub the under side of the overhead conductor ; currents up to 3,000 amperes can thus be collected at 30 miles per hour, and 2,000 amperes at 60 miles per hour, and the wear on the conductor is trifling. [British practice, on service of much lighter character, has generally followed the third-rail system, with various types of collecting shoes, the side and under-running types being favoured for recent work.] Where long grades are met with, regeneration affords a valuable economy ; it has been shown that on a gradient of 2 per cent. as much as 42 per cent. of the power required to haul a train up the gradient can be recovered on the descent.

LONDON TUBE RAILWAYS SYSTEM.

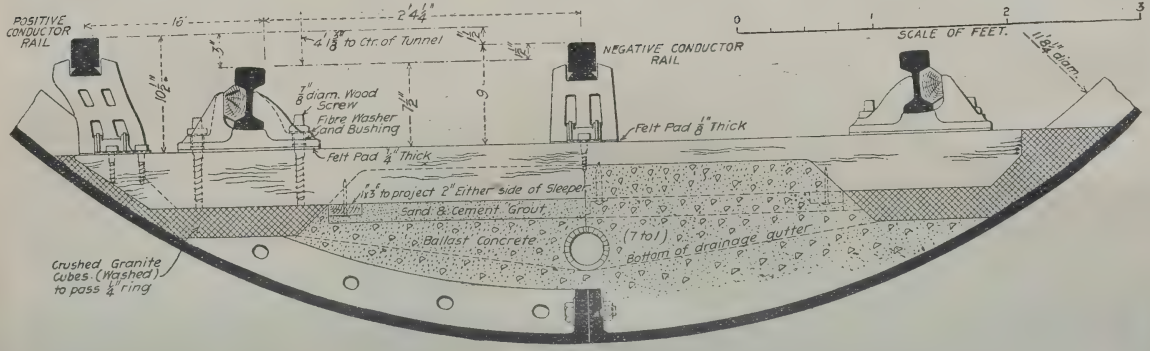

FIG. 1.—Type of Construction of Permanent Way and Conductor Rails.

The length of electrically equipped British railways at the end of 1918 was 351 miles (mainly suburban), and the consumption of electricity for traction in 1918 was about 400 million kw.-hrs., at an annual one-hour load factor of 37 per cent. The total consumption of electricity by fourteen railways for traction, light, and power was 517 million kw.-hrs., at a load factor of 34 per cent.; but for the war this figure would have been raised to 875 million kw.-hrs. It has been estimated that to electrify all the railways in Great Britain would cost 300,000,000*l.*, and that an annual saving of 7,000,000 tons of coal would be effected thereby.

(*Roger T. Smith.*)

It is estimated, on the basis of the results of five years' working of the Chicago, Milwaukee and St. Paul Railway, that if the whole of the United States railways were electrically operated, 122,500,000 tons of coal (two-thirds of the coal now used for railway traction) would be saved, without allowing for the further saving due to the use of water-power. The power-station capacity required would be 10 million kilowatts (about half the capacity of the existing power stations in the United States).

At a paper read before the Institution of Locomotive Engineers, it was stated that taking 2 lbs. of coal in power station to produce 1 kw.-hr.; efficiency of transmission of power to drawbar 62 per cent.; this gives 3·2 lbs. of coal per kw.-hr., or 2·4 lbs. per h.p.-hr., at drawbar of electric locomotive. For the ordinary steam locomotives the figure varies from 4 lbs. to 8 lbs. per h.p.-hr. at drawbar.

The tendency in recent years has been towards the adoption of high-pressure direct current for main-line traction in the United States and France. On the other hand, single-phase alternating current is preferred in Germany, Sweden (which has 400 miles S.P., and only 20 miles D.C.), and other continental countries. Italy, however, has 390 km. of three-phase line, and is using that system for most new construction.

In the United Kingdom the choice of system for future construction has been settled by the report abridged below.

Standards for Railway Electrification

The Electrification of Railways Advisory Committee, appointed by the Minister of Transport in March 1920, issued its final report in September 1921, recommending that all new electrification should be on the direct-current system, and that the standard pressure should be 1,500 volts, except in the case of railways already operating at 600 or 1,200 volts D.C., or with alternating current. The adoption of 750 or 3,000 volts should be permitted where approved by the Minister. Both overhead and rail conductor collection were recommended, provided that the form and design of the conductors and structures were in accordance with specified regulations. Current should be generated on the three-phase system, at the frequency in general use in the district concerned; 50 cycles could be used satisfactorily. Suggested regulations were given, with drawings, for the standardisation of contact rails, the centres of which were to be 16 in. from the gauge line of nearest track rail, and for top-contact 3 ins., for under-contact 1½ ins., above the plane of the top table of the track rails. The clearance of the contact shoe in the free position over the track rails was not to be less than 1½ ins. For overhead collection, the clearance between the overhead conductor and the maximum load gauge was to be 3 ft. in the open and 10 ins. in tunnels and under bridges; between the conductor and any part of the structures, 6 ins.; between the conductor and the rail level 18 ft. at crossings, 20 ft. where men might have to stand on the roofs of vehicles; and between any part of the collector gear and any structure, 3 ins. Exceptions were made in the case of the equipment of existing lines.

The contact wire was to be not more than 15 ins. from the vertical plane through the centre line of track at 18 ft. above rail level, and provision should be made for an upward pressure of 25 to 40 lbs. The contact surfaces of collectors were to be not less than 4 ft. wide, and the extreme width of collectors not more than 7 ft. 6 ins. The Committee considered it undesirable to set limits to the drop of pressure in uninsulated return conductors.

Tramway Tyres and Axles.

The British Engineering Standards Association has issued standard specifications Nos. 101—1921 for tramway tyres and 102—1921 for axles. The former includes particulars of the tests to be applied, and a drawing showing the shape and dimensions of the tyre of standard section. The latter specifies that the steel shall not contain more than 0·05 per cent. of sulphur or phosphorus, and defines the tests to which the axle shall be subjected.

New tyres should be turned to the same angle of inclination as the worn head of the tramway rails has assumed, and care should be taken to ensure that the tyres fixed on the same axle should be of equal hardness, in order to ensure the maintenance of equal diameters in service.

TRAMWAY RAILS.

In Great Britain the grooved girder rail is practically the only type employed for tramways constructed in public roadways.

At Hull the rail used has a double tread with central groove. This form involves the use of more current in propelling cars.

On some inter-urban tramways, with tracks laid on private lands, ' tee ' section rails have been used, loose guard-pieces being bolted on at curves ; on single lines, having passing places with automatically worked points, ' tee ' rails present practical difficulties, and the later tendency is to use a special type of the ordinary grooved girder rail for such lines.

Twenty to thirty per cent. more power is required to run cars on a grooved rail than on a ' tee ' rail, due to side friction, dirt in grooves, &c.

When gauge is 4 ft. or less, in order to allow room for removing motors, special rails, without overhang, should be fixed at car pits.

Weight of straight-track rails used in this country varies from 65 lbs. per yard, as at Coventry and Norwich, to 108½ lbs. per yard, as at Sheffield, Leeds, Wigan, &c. Rails of from 90 to 105 lbs. per yard are now generally adopted, with depth from 6 ins. to 7 ins., and width of base 6½ ins. to 7½ ins. In America, rails weighing as much as 137 lbs. per yard are now being used.

The Board of Trade has made a pronouncement against the employment of rails less than 90 lbs. per yard.

For a wheel flange ⅞ in. thick, groove width should be 1½ in. on straight, and 1¼ in. on curves less than 75 ft. radius.

It is of importance that the profile of wheel tread and flange should accord to the shape of rail table and groove.

On curves of less radius than 50 ft. there is much grinding of wheel flange against both sides of groove which quickly widens under such wear ; to allow for this the guard or lip on curve rails should be made thicker and higher and rails should be preferably of manganese steel.

Curves less than 100 ft. radius should be of spiralised or other easement form.

The top of guard or lip for straight-track rails is usually made slightly lower than the table, to allow for greater wear on latter, but the effect of this is very objectionable to vehicular traffic where the rail table is not sloped or coned.

The rail web should be as nearly as practicable under the centre of rail table, so that the resultant of forces, due to rolling load of car and lateral pressure of wheel flange, shall fall well within the rail base, otherwise there is a tendency for the rail to tilt sideways.

The base should be sufficiently wide to spread the superincumbent weight on to the underbed, and to resist the side-tilting motion.

The British Engineering Standards Association has issued a series (No. 2—1903) of fully-dimensioned drawings for ' British Standard ' (to be known as ' B.S.') tramway-rail and fishplate sections, and also for corresponding standard tyre profiles for tramcar wheels. A Report (No. 79—1919) has been issued by the Association on British standard special trackwork for tramways.

Fig. 2, page 673, shows a section of a 105 lb. (No. 4) rail.

Expert opinion, and the actual practice of some authorities, now favours the use of a deeper groove, viz. 1½ ins., than is shown in fig. 2.

There are five sections of rails for straight tracks, with corresponding sections for curved tracks. The fishplate sections are similar for both sets of rails. Their general particulars are as shown by the table below.

The affix C to the ' B.S.' number denotes that the rail is for use on curves, the difference between the straight-track and curve rails being that the groove is ¼ in. wider and the guard or lip thicker and higher in the latter. All the sections have heads of identical profile as regards the groove and the angle of the rail-table. This profile gives a groove 1⅛ in. wide by 1¼ in. deep, measured from the highest point of the table, which has a slope of 1 in 21. The guard or lip is ⅛ in. below the highest point of the table. In the curve rails the groove is 1½ in. wide, and the lip is brought up level with the table. The only difference in the profile of tyres for running on the various sections, is in the width of the tread to suit the varying widths of rail-table—i.e. from 1⅞ in. in Nos. 1 and 1C. to 2¼ ins. in Nos. 5 and 5C.

TABLE OF TRAMWAY RAILS.

'B.S.' Section.	Rails.			Fishplates.	
	Height.	Width of Base.	Normal Weight per Lineal Yd.	Weight of Inner.	Weight of Outer.
Number	Ins.	Ins.	Lbs.	Lbs.	Lbs.
1 } 1c }	6½	6½	{ 90 } { 96 }	22½	27½

4 } 4c }	7	7	{ 105 } { 111 }	26	30½
5 } 5c }	7	7	{ 110 } { 116 }	26	30½

BRITISH STANDARD SECTION TRAMWAY RAIL.

'B.S.' Section No. 4.—105 lbs. per yd.

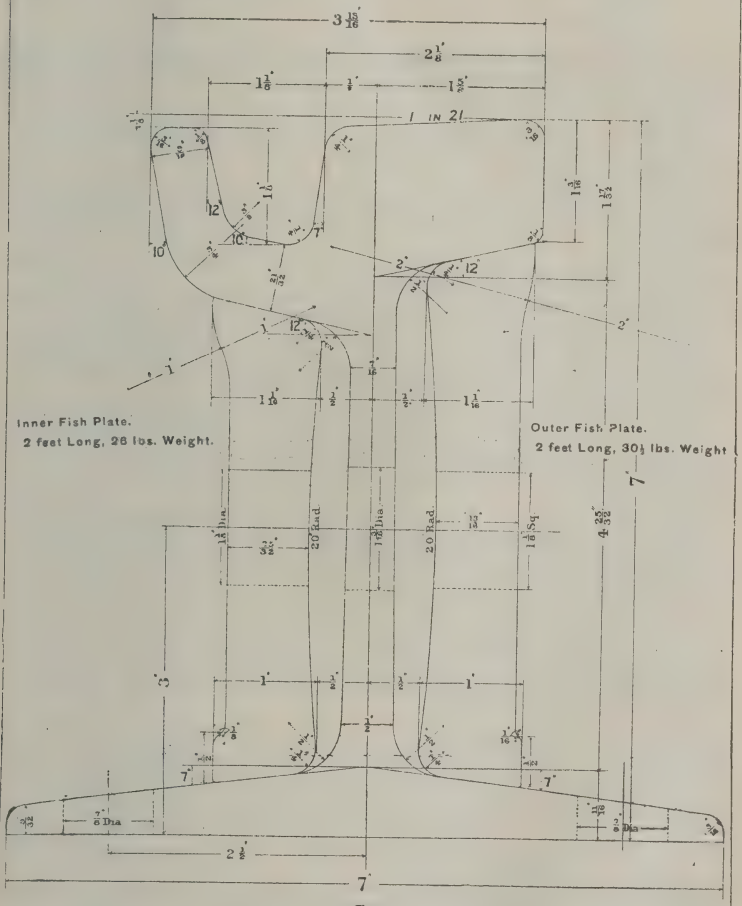

FIG. 2.

Electrical resistance per yard of rail (single) = ·0000276 ohm = ·0486 ohm per mile,
= 11·8 times resistance of a copper conductor of same section.

The Association has likewise drawn up a Standard Specification for manufacture of tramway rails, prescribing the chemical constituents, physical tests, etc. The principal provisions are briefly as follows :—

Chemical composition.—Steel to conform to following limits :

Carbon	from 0·40 to 0·55 per cent.
Manganese	„ 0·70 „ 1·00 „
Silicon	maximum 0·10 „
Phosphorus	„ 0·08 „
Sulphur	„ 0·08 „

Manufacturer to furnish carbon determinations of each cast, and a complete chemical analysis for each rolling, or, if a rolling exceeds 100 tons, for each 100 tons or part thereof. Engineer may make independent analyses ; in case of difference, samples may be analysed by an independent metallurgist, to be mutually agreed upon.

Templates.—Two complete sets of templates are to be furnished, properly engraved with names of purchaser and manufacturer, 'B.S.' number of section, weight of rail, and date of contract.

Limits of variation.—Permissible variations are $\frac{1}{32}$ in. under or over total height, but $\frac{1}{64}$ in. only between fishing-angles.

Lengths.—Normal for straight track to be either 35 ft., 45 ft., or 60 ft., maximum proportion of short lengths being 7½ per cent. for the 35-ft., 10 per cent. for the 45-ft., and 15 per cent. for the 60-ft. lengths. For curved tracks the normal length to be 35 ft., with 10 per cent. of short lengths.

A variation of ¼ in. either way is permitted in the lengths. All short lengths to be painted white at each end, and have their lengths painted on.

Straightness and squareness.—All rails to be made properly straight and true in all directions. When cold, to be sawn or planed true and square, and burrs removed before leaving the works.

Branding.—A special brand is to be rolled on the web of every rail, to indicate that the rail is of 'British Standard' section and made under the conditions of the Standard Specification ; also the number of section, weight, manufacturer's name or mark, and year of manufacture. The number of cast or blow is also to be stamped on the end of each rail.

Impact test.—A 5-ft. test-piece, head uppermost, is to be supported horizontally on solid iron bearings 3 ft. 6 in. apart in the clear, and a tup or ball, having 9 ins. radius face and weighing not less than 1 ton, dropped on to it, midway between the bearings, from a height of 15 ft. for rails under 100 lbs. per yard, and of 18 ft. for rails of 100 lbs. and over per yard. If the rail fractures, all from that cast may be rejected, unless it is shown by a similar test on two further pieces that the first was not fairly representative of the quality of the steel. One rail in eighty may be selected for this test.

Tensile test.—From each 100 tons of rails a rail may be selected and a test-piece cut therefrom. This piece is to be machined to a sectional area of half a square inch and a length of 2 inches between test-gauge points. It is to show an ultimate tensile strength equal to not less than 40 tons per square inch, with an elongation of not less than 12 per cent. on a length of 2 inches. In case of failure another rail from the same cast may be tested, and if that also fails the whole of the rails from the cast may be rejected.

Bending.—From each 100 tons of rails a selected rail is to be tested by bending sideways to a curve of 30 ft. radius, and shall not show signs of cracking ; if it does, two more rails are to be bent, and if they fail the whole rolled from that cast may be rejected.

Acceptance.—On the rejection of any cast, the acceptance of the rails from the other casts forming the lot of 100 tons from which the sample was selected will depend upon the passing of similar tests of a rail from each cast.

Holes in rails.—If required, each rail is to have holes made in it, without extra charge, for fish-bolts, electric bonds, tie-bars, joint-plates, and intermediate holding-down plates. Those for the tie-bars may be punched, but all others must be drilled. The size, number, and position of these holes are specified, and the limits of permissible error in position and diameter set out.

Notice and facilities for inspection.—Seven clear days' notice of the rolling of the first lot and three days for subsequent rollings is to be given ; the inspector is to have access at all working hours to those parts of the mill where work under his inspection is being performed. The manufacturer is to provide all necessary apparatus in complete working order, and to provide all labour and reasonable assistance for making the specified tests. All rails accepted are to be stamped by or in the presence of the inspector.

Payment by weight.—Rails are to be paid for according to actual weights before drilling or punching, weights to be ascertained by weighing sample rails not less than 30 ft. long.

Fish-plates.—The chemical composition of the steel, tensile tests, and general conditions as to manufacture of rails, also apply to fish-plates. Accuracy of fit between rails and fish-plates is regarded as of special importance, and sample joints are to be made whenever the engineer or inspector desires to test this.

Bending.—When cold and before being punched, the fish-plates shall be capable of being bent to a right angle round a bar 4 ins. in diameter without showing fracture.

Size.—Length, 24 ins., ends sawn square.

Holes are to correspond with those in the rails. In the outer plates the holes to be 1¼ in. square and in the inner 1⅛ in. dia. All burrs are to be removed, and if fish-plates have been punched cold they are to be afterwards annealed. If necessary, after punching they are to be straightened between dies, and any bulge completely removed. They are to be dipped into hot boiled linseed oil or other approved liquid, and if required wired up in bundles. Rejected fish-plates are to be destroyed, and payment is to be according to actual weights.

(Copies of the complete specification and drawings can be obtained from the offices of the British Engineering Standards Association, 28 Victoria Street, S.W. 1.)

Notes on Chemical Constituents and Physical Tests of Tram-Rails.

Generally speaking, there are very wide variations in the specified stipulations as to the chemical constituents of steel for tramway rails, particularly with regard to the proportion of *carbon*, which may be regarded as the main hardening constituent, some engineers specifying this to be as low as from ·28 to ·40 per cent., while the highest extreme is from ·55 to ·65 per cent. It is questionable whether the latter stipulation always meets with full compliance.

Where British ores are employed, there are limitations in practicability of manufacture of very high carbon tramway rails.

If carbon is over ·55, and especially if combined with high silicon, a somewhat brittle rail is likely to result.

Practical experiments under everyday conditions have shown that high carbon tram-rails have not given as good wear as those with moderate carbon.

Rails vary in hardness among themselves even when manufactured to the same specification and subjected to the same tests, and they show corresponding irregularities in their wear, which also varies greatly according to the situation in which rails are placed.

High carbon rails are specially liable to injury by injudicious thermal treatment in rolling.

Carbon and *Manganese*, particularly the latter, notably affect the electrical conductivity of steel, which in tramway rails usually varies from one-twelfth to one-fourteenth that of copper.

High manganese tends to coarse crystallisation, with resulting abrasion and flow of metal, or 'rolling out,' under heavy car traffic. This is often the cause of much trouble from hog-backing, &c.

Sulphur, when in moderate excess, is not particularly harmful, as hitherto generally supposed, but an excess of *Phosphorus* tends to brittleness.

A high percentage of sulphur mainly affects the rail-maker, causing red shortness and seamy metal with attendant difficulties in rolling.

In American standard specifications no limit of sulphur is specified.

Copper.—No limit necessary. It has been conclusively proved that it exercises no deleterious influence even when present in greater proportions than usually found in tram-rail steel.

Arsenic and Nickel.—Limiting proportions are occasionally specified, but for present processes of manufacture it is superfluous to mention these elements. There are propositions, however, to employ nickel to a greater extent in rail-steel making.

The processes usually employed in analysing the chemical constituents of steel are not so exact as for the physical tests. There is also considerable liability to personal error. The effects of segregation of the constituents often have an important bearing in the consideration of this question. Carbon is sometimes judged by the colour test, but more exactly by the combustion test.

Physical Tests.—The impact, or drop, test when conducted by a thoroughly competent inspector is perhaps the most valuable of all tests for ascertaining the general quality and characteristics of the steel in tramway rails.

As deflection is in the nature of a measure of ductility of a rail, and as tramway rails are composed of chemical constituents with a view to securing extreme hardness in the steel—which is not compatible with great ductility—it is not usually considered desirable to exact a deflection test.

Steels of similar chemical constituents, but manufactured by different processes, will give somewhat different results in the physical tests. A high elastic limit is one of the most important properties of tram-rail steel, and can be obtained, combined with toughness, by suitable heat treatment.

The physical tests stipulated by specifications are often incompatible with the required chemical constituents of the steel and the processes to be employed in its manufacture.

The results of the chemical analyses and physical tests should be considered in conjunction.

Inspection.—It is of very great importance that there should always be careful inspection and testing of tramway rails, conducted by a thoroughly competent and reliable inspector, at the rolling-mills, before acceptance of deliveries.

Sandberg Rails.

The use of Sandberg silicon steel (silicon 0·3, carbon 0·5, manganese 1·1 per cent.) increases the life of rails by at least 25 per cent. If steel of the same composition is treated by a special process (Sandberg air-cooled steel), the life is said to be increased by 100 to 200 per cent., so far as experience has been obtained (*R. B. Holt*). The surface of rails can be hardened *in situ* by a patented process which has been adopted on several British tramways; this process diminishes the tendency to corrugation.

Rolling-Mill Memoranda.

The Bessemer basic process of steel-making is now generally employed for the manufacture of tramway rails at English and Continental rolling-mills.

Rails are cut, while hot, by circular saw, to specified lengths, with a certain margin for shrinkage in cooling. They should be cut off quite square at the ends; the practice of undercutting below the head should not be permitted.

Very exact or dead lengths require to be planed in an ending or milling machine, and are usually subject to a slight extra charge.

Rails are straightened, while in a cold state, in a press.

45 ft. or 60 ft. are the most usual lengths. With the latter there are fewer joints, and they are generally preferred.

Density of Steel for Girder Tram-rails.

As a result of very careful and complete experiments and tests, undertaken at the instance of the Engineering Standards Association at the National Physical Laboratory, it was found that the average density of the steel in a large number of specimens of English-made tram-rails was 0·283 lb. per cubic inch.

Sectional area of rail in square inches=approximately one-tenth the weight of rail in lbs. per yard.

Rail Joints.

This detail is of the first importance, as the rail joints are the weakest part of the track and determine its life, being also the main factor in the cost of maintenance of the permanent way, and largely affecting the cost of upkeep of the rolling-stock and equipment.

A thoroughly strong and permanently rigid joint will maintain a smooth and quiet running surface, and will greatly lengthen the life of the rails, while assisting the electrical conductivity.

Fishplates alone, even when of the heaviest type, have proved inadequate to withstand the stress from the great vibration and pounding effect experienced from the running of heavy electrical cars, and the addition of flat plates under the rail-base has proved of no permanent advantage.

The very best type of joint should be employed, such as an efficient form of bridge joint. A type frequently adopted is the Cooper patent 'Anchor' joint, which is in the form of an inverted rail or joist riveted to the under side of the rail-base, thereby having the effect of doubling the depth of the rail about its weakest part. This device, in addition to providing an efficient connection between the rail-ends, also securely holds the rails down to the concrete foundation, thus keeping them rigidly in position and preventing springing, creep, etc. It is also of considerable value in providing a path for the electric return current.

Allied to the question of rail-joints is that of fixing down or anchoring the rails to the concrete under-bed, not only at the rail-ends, but at intervals intermediately. When rails are welded together, anchorage at close intervals is certainly a necessary accompaniment. At Leeds, with the 'thermit' process, the rails are anchored at 8-ft. intervals.

Taking into consideration the increased length of rails, the close-butting of ends, and other circumstances, this course is undoubtedly essential to provide against the effects from expansion and contraction, hog-backing, creep, springing, undulation, vibration, water-pumping, cold-rolling, spreading of gauge, and other causes tending to create movement in the rails.

The distance apart for intermediate anchors or holding-down devices varies from 3 ft. 6 ins., as at Hull, to 30 ft. There should be at least one intermediate with 45-ft. rails, and two with 60-ft. rails.

Rails should not be rigidly connected to each other across the track—as, for instance, by steel cross sleepers fixed under rail-base from rail to rail—as this is liable to cause waviness in the rail-table, due to unequal flexure in the rails.

Worn rails can be ground to shape *in situ* by a travelling apparatus, thus prolonging their life by several years. Worn joints can be built up to level by adding metal with the metallic arc.

Foundation.

In the most approved British methods of electric-tramway construction, the base of the rails is bedded on a foundation of concrete, composed of 6 parts of stone and sand to 1 part of Portland cement, laid about 20 ins. wider than the gauge of the track, and 6 ins. in depth, a short length of some 3 ft. under the rail-joints being usually made from 3 ins. to 6 ins. deeper and of better quality concrete. The latter should be of clean aggregate mixed with good quality cement having somewhat quick-setting properties.

Sometimes the concrete is first laid, the rails being afterwards set, and packed to the required level with small crushed stone and cement, mixed dry. A more approved method is first to set the rails on blocks to the proper alignment and level, and to fit all the fastenings, afterwards placing the concrete in position under and around the rail-base, care being taken that there shall always be a sufficient 'head' on the upper surface of concrete above the rail-base.

At Hull, a longitudinal timber, 4 ins. thick and the width of rail-base, is interposed between the rails and the concrete. At Aberdeen, on part of the track, cross-sleepers are used.

The hollow on each side of the rail-web should be filled with a 'parging,' or rendering composed of 1 of cement to 4 of sand, laid to a vertical surface to pave against.

Rails should be laid so as to butt quite close at ends.

Points and Crossings.

Points and crossings should be of manganese steel throughout, or, if of the best crucible cast steel, then with specially hardened tongues. Renewable parts are of questionable value. Points should be about 12 ft. in length, having one road curved. The tongues should be at least 6 ins. longer than maximum wheel-base length of cars. Movable points should always be drained. Crossings should be of the 'leg' type, and from 7 ft. to 8 ft. long, according to angle number.

Drain-rails should never be used, but slots 9 ins. long cut in rail-groove at every low point, and trapped drain-boxes fixed and connected to sewer.

Cost of Construction.

Where the overhead running or trolley principle was adopted, the pre-war cost of construction of the permanent way varied approximately between 4,500*l.* and 6,500*l.* per mile of single track, this variation being mainly due to the different classes of paving used. Present prices are about 250 per cent. higher.

A fair general average of proportionate costs over a system may be taken as follows :—Rails and fastenings, including points, crossings and special work, 30 per cent.; paving (sett or wood) including concrete underbed, 45 (to 50) per cent.; labour, including cartage, 20 per cent.; bonding, 2 per cent.; watching and sundries, 3 per cent.

Tractive Resistance on Tramways.

The average pull required per ton of load to keep a car moving is 30 lbs. With exceptionally clean rails, as during a heavy rainfall, and with the rail grooves void of dirt, the pull may be as low as 20 lbs. per ton, or below this figure, approximating to the 10 or 12 lbs. of railway work. Again, a very dirty, clogged rail may demand more than the 30 lbs. Multiplying the pull by the speed in feet per minute gives the power in foot-pounds per minute, so that the horse-power is $\text{H.P.} = \frac{T \times W \times S}{33{,}000}$, where T is the pull per ton necessary, W is the load in tons, and S the speed in feet per minute. This rule gives the horse-power on the level. To find the power on a grade, the vertical rise of the car is found by dividing the speed of the car in feet per minute by the length of road in which there is a rise of 1 foot. The number of feet of vertical lift multiplied by the total weight in pounds gives the work done per minute against gravity, or $\frac{S \times W}{F}$, where W is the load, S is the speed, and F is the distance in which the road rises 1 foot. Thus on a 1 in 30 grade, F = 30. The addition of the two results gives the total horse-power.

Tramway Motor Control.

CONNECTIONS OF MOTORS IN SERIES-PARALLEL, WITH CUT-OUT OF RESISTANCES, ON BRITISH WESTINGHOUSE CO.'S 'T' TYPE TRAMWAY CONTROLLER.

The method now universally used for controlling the motors on an electric tram-car is that known as the series-parallel system. With this system the two motors are first thrown on to the line in series with one another and with a resistance. This resistance is gradually cut out by the operation of the controller until the two motors are left in series without any resistance in the circuit. The motors are then thrown in parallel with a resistance in the circuit, and when this resistance is finally cut out the motors are in full parallel.

Fig. 3 shows the various combinations as the handle of the controller is moved over.

First Point.—Current passes from the trolley through six sections of resistance, through Armature No. 1, and Field No. 1, thence through Armature No. 2, and Field No. 2 to ground.

Second Point.—Two sections of resistance are cut out.

Third Point.—Two more sections of resistance are cut out.

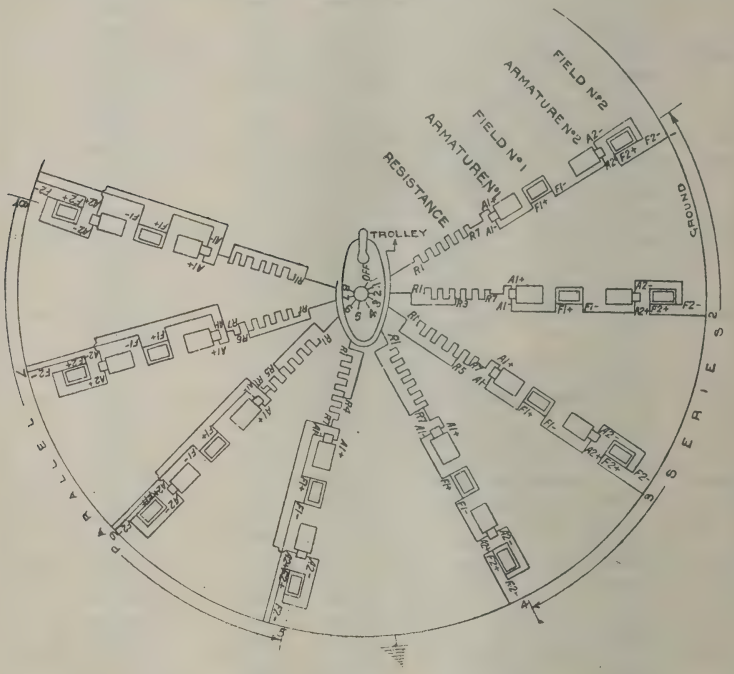

FIG. 3.

Fourth Point.—Two more sections of resistance cut out. The motors are now in full series on the line with no resistance in circuit.

Fifth Point.—Current passes from the line through three sections of resistance and thence to ground through the two motors in parallel. The armature and field of each motor remain of course permanently in series with one another on all combinations of the controller.

Sixth Point.—One of the sections of resistance is cut out.

Seventh Point.—Another of the sections of resistance is cut out.

Eighth Point.—The remaining section of resistance is cut out, leaving the two motors in full parallel on the line with no resistance in circuit.

ELECTRIC EQUIPMENT OF TRAMWAYS.

Sectioning.

Trolley lines must be divided up into sections not exceeding half a mile in length by means of section insulators. The usual method of feeding the separate sections is to bring the supply cables to a small switch-board fixed in a cast-iron box near the poles carrying the section insulators. The supply cable is connected through a switch to a bus bar from which the four leads to the trolley lines are taken. Another method of feeding is to have a small section pillar in the middle of each section, into which the feeder is brought, and thence to feeder cars on the trolley wire. On the poles carrying the section insulators small iron boxes are fixed, carrying two single-pole switches connected to the section insulators. These switches are normally in the off position, so that in the event of a breakdown in the trolley line it is only necessary to go to one box in the centre of the section instead of two half a mile apart. In the event of failure on a cable, the section switches can be closed and the line run on the trolley wire alone.

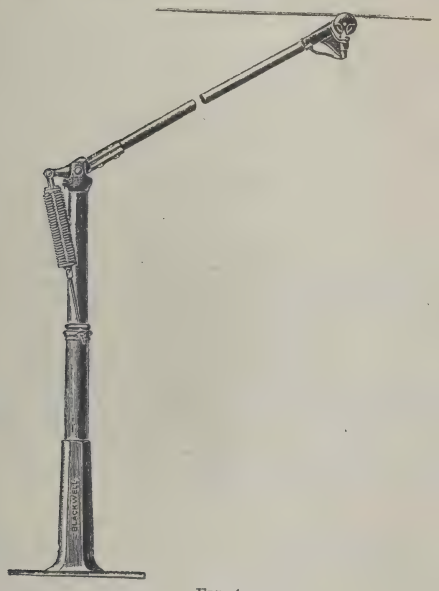

FIG. 4.

All large and complicated junctions are generally isolated by means of section insulators on each line, placed as near the junction as possible, the junction being fed separately. This enables such a section to be isolated by the pulling out of one switch, and repairs can be made quickly and without shutting down the service.

Section boxes should be placed as close as possible to the poles up which the side-feed cables are carried. The simplest method of carrying the side-feeds from the box to the pole consists of a short piece of pipe passing from the section-box to the inside of the pole and held by lock-nuts to the section box. This method enables the cables to be easily withdrawn without disturbing the pavement, and also gets over the danger of the cables lying in water at the foot of the pole, as is frequently the case where they are carried underground.

The side-feed cables generally consist of rubber-insulated flexible-stranded cables, 2,500 megohm grade, and are protected by means of wooden brushes where they enter and leave the poles. The four cables should be tightly taped along their whole length to the span or bracket arm which carries them with 'P. & B.' tape or other weatherproof material. This gives them a neat appearance, and greatly increases the life of the cables. Paper-lead cables should on no account be used for side-feeds, as the lead frequently causes trouble. In some towns bare wires

are used instead of rubber-covered cables, but the arrangement has an untidy appearance and possesses no advantages.

The system most in use at the present is known as the single-trolley system, the current being collected from the overhead wires and returned through the rails. In some few cases, where the earth-return current is likely to affect delicate scientific instruments, two overhead wires are carried over each track, one being the feeder and the other the return. This system, however, involves complications at junctions owing to the necessity of extra insulation between the feed and return wires, and the large number of wires required.

Trolleys.

Fig. 4 shows a Blackwell trolley with outside springs. This is the most simple form of trolley, as all springs are easily examined and adjusted. The cable is carried down the inside of the trolley arm to the bottom of the standard. The connection to the car leads is made by means

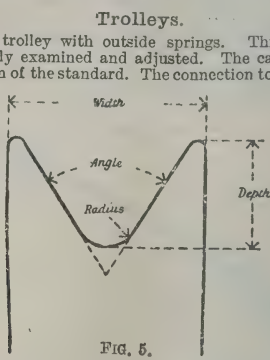

FIG. 5.

of revolving rings or fixed-ring collector and a revolving brush, which allows the arm to make a complete revolution. In the Blackwell trolley with inside springs the springs are entirely enclosed, and are easily adjusted by means of one tension rod. This type has the advantage of taking up less room than the outside spring type.

THE TROLLEY WHEEL.

Trolley wheels should be of a good quality metal, but not too hard, as a worn wheel can be more easily replaced than a worn wire. Some trolley lines have been ruined by the manager, or other person responsible for the trolleys, endeavouring to get a high mileage out of the wheels.

The trolley wheel is usually about 4 ins. over all in diameter, of gun-metal or other copper alloy, and is fitted with a bush filled with some graphitic compound. The following are the dimensions recommended by the British Engineering Standards Association (No. 23—1905) as the section of the standard trolley wheel grooves (fig. 5): Width in inches $= 1\frac{1}{8}$; depth in inches $= \frac{3}{4}$; radius in inches $= \frac{7}{32}$; angle in degrees $= 65°$.

Overhead Construction.

The types generally in use are span, single-side bracket, double-side bracket, and centre pole. The span system is the best from the line point of view, as it allows the greatest flexibility, and also allows the wire to be placed centrally over each track, thus ensuring an even wear on the wire and a smaller tension on the trolleys. It has, however, the disadvantage of requiring standards

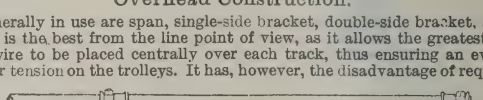

FIG. 6.

on both sides of the streets; and in many cases this is impossible owing to telegraph lines or other causes. Double bracket arms are used in some cases where the lines are laid close to the kerb on both sides and where span wires across the street would be of excessive length.

The single-side bracket is the form of construction most generally in use where economy is of importance and in cases where there are difficulties in obtaining room for structures on both sides of streets. Side brackets up to 22 ft. long have been used in some instances, but such long arms should only be used in very exceptional cases. The Board of Trade Memorandum (see page 689) limits the length of the arms to 16 ft. maximum. Where bracket arms are used, the trolley wire should be suspended by means of flexible suspensions, as in fig. 6. These

consist of a short length of stranded-steel wire strained between two suitable malleable cast-iron or wrought-iron brackets bolted to the bracket arm. This length of wire should not be strained too tight, as it then becomes a practically rigid suspension; neither should it be left sufficiently slack for there to be any danger of the line being lifted by a trolley so that the insulator casting comes in contact with the bracket, and so cuts out the second insulation.

Trolley Wire Fittings.

The standard practice is to use double insulation in all cases on trolley lines, the usual method being an insulated bolt fitted into the hangers, the second insulator being either a Globe Insulator or Brooklyn Strain at each end of the spans. All spans should be fitted either with one or two Brooklyn Strains in order to provide adjustment of the span wires. In some instances porcelain or earthenware spool insulators are used instead of Globe Strains; but as the saving in cost is very slight and there is a greater risk of breakage, it is not regarded as good practice. The most usual types of insulators are the straight line hanger and the double and the single pull-off for use on curves. The metal portion of the insulators is either of malleable cast iron or gunmetal, the latter being more expensive in first cost but cheaper to maintain, as it does not require painting. In the Blackwell type of section insulator it is unnecessary to anchor the trolley wire over the top of the insulator.

The usual method of attaching the trolley wires to the suspension insulator is by sweating them into gunmetal ears. Where sweating is adopted the ears should be accurately milled out to take the wire, and the lips of the ears which clip round the wire should be carefully hammered over before soldering, and the ears dressed off to a feather edge after soldering, great care being taken not to notch the wire where it leaves the ear. In all cases it is absolutely essential that the wire should be held in a strong soldering clamp during the whole process of soldering until the ear is cooled. Unfortunately this practice is insisted on only in cases where the work is carried out by experienced contractors; and in many cases where corporations do their own work the sweating clamp is considered unnecessary, with the result that breakages of the wire at ears frequently occur. The sweating of the ears naturally causes the wire to be annealed, and this also is a cause of breakages.

The most satisfactory arrangement is to have the ears carefully hammered along the wire and the ends dressed off and left unsoldered. For some reason, however, this method is seldom specified, though not infrequently it is adopted in actual construction. In many cases mechanical bars are used. These are made in two halves, bolted together, and grip the trolley wire by means of a V-shaped groove drawn in the wire slightly above the centre line. This method facilitates erection, avoids softening the wire by sweating, and gives a straighter path to the trolley at the ears. It has, however, the disadvantage that the wire has to be annealed in order that the groove may be drawn into it, and the breaking strain of a grooved wire is less than that of a circular wire; there is also a tendency for the groove to turn over between the points of support, causing the wheel to run badly and frequently to leave the wire on curves. Guards should be fixed at all frogs and on both sides of all crossings to prevent the trolleys jamming in the angles, as, in addition to their being a great safeguard, they help to preserve the wire, as the wear is taken up by the mechanical ears which support the roller bars, and these are easily renewable.

Poles.

Poles are usually 31 ft. long, and are planted 6 ft. in the ground, sufficient rake being allowed in erection so that the pole stands nearly vertical with a slight backward rake when the span and trolley wires are on. The amount of rake for a 36-ft. road in good ground should be about 6 ins., but the actual rake required varies with every class of ground, and can only be successfully estimated by experienced men. The holes should have a sufficient diameter to allow of six inches of concrete round the pole in good ground; this must be increased in bad ground or at places where additional loads are imposed due to bridles, extra long spans, etc. The poles should be planted on circular discs of concrete, or on flagstones or cast-iron plates dropped into the holes to prevent the poles cutting into the ground during erection. The holes should be filled in with 6 to 1 concrete, well rammed. In order to prevent corrosion, all poles should be coated inside and for a distance of 8 ft. from butt outside with hot tar or Angus Smith composition.

In the specification for tramway poles, page 691, the light pole is suitable either for short side brackets or centre pole work, the medium pole for long brackets or span construction, and the heavy pole for anchors and pull-off poles. Three-section poles are generally used, as they are cheaper and more reliable than taper poles. Owing to the irregularity of the taper, the fitting of brackets, pole straps, etc., is extremely difficult with taper poles, and their appearance when erected hardly differs from the three-section pole.

Trolley Wire.

Trolley wire is usually 0 (·324 in.), 00 (·348 in.), or 000 (·372 in.) S.W.G., of hard drawn copper; conductivity should be 98 per cent. of pure copper; it should bear an elongation of 1½ per cent. in 10 inches, a breaking strain of 25 tons per square inch, and 20 twists in a length of 12 inches. The lowest point of the wire should not be less than 17 feet from the road surface.

The Engineering Standards Association recommends that the tensile breaking strength should be not less than 24 tons per square inch, up to No. 00 S.W.G., and not less than 22 tons above that gauge.

If L = distance in feet from pole to pole; l = actual length in feet of one span of trolley wire; d = dip in feet; T = tension in lbs. in trolley wire at point of support; w = weight in lbs. per foot of wire; then

$$d = \frac{L^2 w}{8T}; \quad T = \frac{L^2 w}{8d}; \quad l = L + \frac{8d^2}{3L}; \quad d = \sqrt{\frac{3Ll - 3L^2}{8}}.$$

If ϵ = expansion coefficient per F° = ·00001; c° = change of temperature; then $l \pm c^\circ \epsilon$ gives the new length on change of temperature = c°, from which the new dip d may then be calculated, or the tension T for any dip. In these formulæ the effect of wind pressure is neglected.

Span Wire.

The steel wire rope to form spans for carrying trolley wire is usually formed of a galvanised strand of 7 No. 12 S.W.G. or 7 No. 15's. The 7/12 is usually specified to bear a breaking strain of about 4,600 to 5,000 lbs. When the 7/15 wire is used it is of much harder material, and weighs 225 lbs. per 1,000 yards. The only objection to the small wire of high tenacity is the difficulty of forming the eyes over the thimbles and nozzling the ends.

Guard Wire.

Guard wire when single is No. 8 S.W.G. steel, and weighs 215 lbs. per 1,000 yards, but it is often of stranded steel. Guard wire brackets in their plainest form are T's of ¾ in. iron pipe clipped on bracket arms. In span systems guard wire is carried by special guard wire spans.

Strength and Conductivity of Wires.

Material.	Conductivity.	Breaking strain, Lbs. per Sq. In.
Commercial copper	98–99	33,000
Hard drawn „	96–97	60,000–65,000
(1) Silicon bronze	97	63,200
(2) „ „	80	76,000
(3) „ „	45	110,000
Phosphor „	26	101.000
Annealed iron	14	55,000
High carbon steel	10–12	120,000–130,000

Rail Bonding.

Except in those comparatively rare cases where a double trolley wire is employed, the rails are made use of as return conductor, and means have to be taken to connect adjacent rails so as to provide an unbroken electrical conductor. To effect this object the rails are bonded with copper, various types of bonds being employed.

The 'Chicago' Bond.

Fig. 9 shows the general design of this bond, which consists of a copper rod having tubular or thimble-shaped terminals bent at right angles to the rod, the whole being composed of one solid piece of copper. The terminals are inserted into holes in the web of the rail, and the slit in the end of the terminal is spread or clinched over on the rail with a hammer and punch. A drift

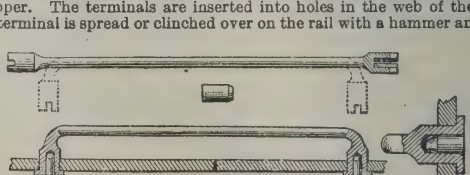

FIG. 9.—Chicago Bond.

pin, larger in diameter than the opening in the terminal by about one-sixteenth of an inch, is then driven in. This permanently expands the terminal and wedges it into contact with the surface of the hole in the web of the rail. The usual length of bond is 30 ins. The depth of the hole in the terminal in all sizes of bond is 1 inch. The size of conductor used depends upon the weight of rail and the current to be carried.

TABLE SHOWING STANDARD DIMENSIONS OF CHICAGO RAIL BONDS.

Size of Wire, B. & S. Gauge.	Diameter of Hole in Rail into which Terminal of Bond fits.	Diameter of Hole in Terminal.	Sectional Area of Rail Bond.	Diameter of Pin.
	Ins.	Ins.	Sq. Ins.	Ins.
0000	$\frac{7}{8}$	$\frac{7}{16}$	·166	$\frac{1}{2}$
000	$\frac{3}{4}$	$\frac{3}{8}$	·132	$\frac{7}{16}$
00	$\frac{5}{8}$	$\frac{5}{16}$	·104	$\frac{3}{8}$
0	$\frac{1}{2}$	$\frac{1}{4}$	·083	$\frac{5}{16}$

The 'Crown' Bond.

FIG. 10.

This is a development of the 'Chicago' bond, the conductors being stranded to afford the flexibility necessary for expansion in a conductor of considerable cross-section dimensions. Fig. 10 shows two of the many different designs in which this bond is made. The terminals have the same dimensions as those in the corresponding 'Chicago' bond.

The 'Neptune' Rail Bond.

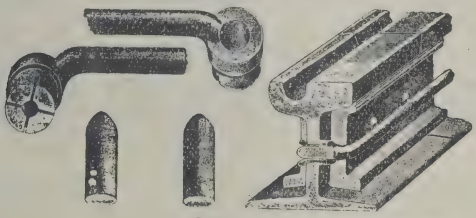

FIG. 11.

Another form of bond, the 'Neptune,' fig. 11, is similar to the 'Chicago,' but the drift pin is driven in the same direction as the bond is inserted, thus safeguarding the bond against being driven out.

The 'Columbia' Rail Bond.

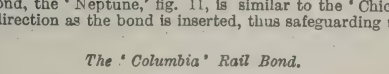

FIG. 12.

A feature in this bond (fig. 12) is the few parts of which it consists. When installed, owing to the pressure exerted between the head and the thimble, and also the fact that they are of the same kind of metal, the two become one, both electrically and mechanically. It therefore has all the advantages which may be claimed for a one-piece bond, and at the same time can be satisfactorily installed, as no riveted bond can be. The contact of the rail and bond is made by a wedge expanding the thimble against the hole in the rail. By using a press, exactly the right pressure is exerted. One blow of a hammer too many or too few frequently spoils contact. As the bond is wedged both ways it cannot get loose, as, owing to the fact of its being pressed in, it is sure to make a perfect contact, and cannot be so over-stretched by hammering as to be ready to fall out at the end of a few weeks. It is essential that the hole in the rail should be clean, and the copper bright also. Bonds ought to be inserted at once after the rails are drilled, no time being allowed for rusting to commence.

Welded Bonds.

The best of all methods of attaching bonds to rails is by electric welding. On this system short bonds can be used, welded into the head or base of the rails outside the fish-plates, or to the webs inside them; the cost of the bond and its attachment is small, and the high conductance of the joint is permanently ensured.

Rail Welding.

Tramway rails are united into continuous lengths by welding. There are two systems in common use for welding rails—the Falk cast weld and the Thermit system. The first consists in casting round the cleaned ends of the two rails a mass of cast iron from a portable cupola. Being buried up to their top table, welded rails are held against contraction from cold, and the full stress does not come upon the weld. Expansion in hot seasons is impossible, and the rails are held against lateral buckling by the support of the paving.

Acetylene Welding.

Acetylene welding by the D.A. system (*The Dissolved Acetylene Co., Ltd.*, now trading as *Allen-Liversidge Ltd.*) has been made considerable use of. The method consists essentially in reinforcing the joints by means of a pressed steel shoe placed on the flange of the rails at the joint and welded to the same so as to constitute a hollow beam which increases the moment of inertia about the joint, and correspondingly diminishes the bending caused by the passage of rolling stock. Many joints of this type have been fitted in France and Algiers and in South America. Experiments in England have been made by various authorities and are now undergoing practical tests.

Thermit Welding.

In Thermit welding a mould is fitted round the rails at the joint, and into it is tapped molten metal from a conical crucible, which is first filled with a mixture of powdered aluminium and iron oxide. The two are intimately mixed, and heated at a point by a special ignition powder. At the temperature produced by igniting this powder, the aluminium reacts very energetically with the oxygen in the iron oxide. The reaction spreads rapidly throughout the mass in the crucible, and produces a quantity of pure superheated liquid metal, covered with a slag of alumina. The temperature set up by the reaction has been ascertained to be about 5,400° Fahr. The crucible is a lined sheet-iron cone. It is suspended over the joint to be welded, and when the reaction is complete it is tapped, the metal running into the mould, followed by the superheated liquid slag, which covers the head of the rail, and raises it to a welding temperature. The rails are then drawn together by suitable clamps, with the result that the base and web of the rails are welded by fusion with the liquid Thermit metal, and the head is butt-welded.

For extra high-carbon rails, the difficulty of butt-welding has been overcome by the use of a special shim, which is inserted between the rail-ends, and ensures a perfect butt-weld at the head.

Electric Welding.

Electric welding has been very widely used, especially in the United States. Two methods have been developed—spot-welding and arc-welding. In the former, bars are placed on both sides of the rails at the joint, and are welded to the webs of the rails by heating them with a very strong current at low pressure, obtained from a transformer, after which the parts are tightly pressed together. These welds are made at several points along the bars. In the latter process, steel plates are welded to the head and foot of the rails with the electric arc, taking the place of fish-plates. In both cases additional bonds are unnecessary, but one is often provided.

(See also 'Welding,' Section XXXVII.)

Cable System.

In English tramway work the cables must be buried. There are four systems in use for buried cables. First, the system of drawing into buried cast-iron pipes. In this system spigot and socket pipes are employed, usually 2 ins. and 2½ ins. inside diameter. A 2-inch pipe 6 ft. long will weigh 48 lbs., a 2½-inch pipe 9 ft. long will weigh 81 lbs. About 2 to 2½ lbs. of lead are required to pour each joint. The pipes terminate in buried brick chambers, in which they are finished with trumpet-shaped ends to facilitate drawing in. On curves the pipes may be slightly curved with advantage, but it is usual to lay the pipes round the curve in an equiangled polygon and to use manhole boxes at such intervals that no length of pipe has a versed sine above 12 ins. Soapstone powder is used as a lubricant. The brick chambers should be built on a good concrete bed with a cement collar joint, and they may advantageously be tarred over outside to render them waterproof. The pipes are bonded across the boxes with a stout iron wire to render them electrically continuous; the boxes have a cast-iron top frame with luted cover. These boxes must be placed at such distances apart that excessive stress is not brought upon the cables when hauling them in. The cables should be gripped by their cores. In place of pipes earthenware conduits are often employed of rectangular or hexagonal shape, in short lengths and cemented at the joints, also terminated in brick chambers. In the solid system the cables are laid in troughs of wood or sheet steel, and melted bitumen is poured over them so as to completely enclose them in a casing of bitumen. Cables are sometimes simply buried in the earth. The best cables are insulated with paper and sheathed in lead about $\frac{1}{16}$ in. to $\frac{1}{8}$ in. thick, squirted on under pressure. In whatever way laid the cables are brought up in their

respective casings through the base of the section box, in which they are connected to the bus bars by switches, so that the cables may be switched out of the circuit in lengths of about half a mile. In the section box are placed the switch terminals of the trolley feeders, which can also be cut out of circuit in half-mile lengths. The trolley feeder cables are carried up inside the next pole, and in the Booth-Dickinson system, brought through the top finial, then down the pole and along the span wire or bracket arm to the trolley wire terminals on the section insulator. Test and telephone wires are usually laid up in one cable and similarly laid in pipes, etc. Sometimes a telephone wire is carried overhead on insulators fixed to the poles. In laying cables and making joints the utmost care is necessary not to expose cable ends to the atmosphere excessively. Tents must be used in wet weather, but it is better to do the work in dry seasons. Cable ends must be well stoppered. It is preferable to have the cable ways under footpaths. The topmost pipe must not be nearer the surface than 18 ins. when laid in the road. Cast-iron pipes or sheet steel conduit must be dipped in Angus Smith compound of a non-brittle variety when cold, and cast-iron pipes should be dipped until they themselves are as hot as the boiling compound. The lead sheathing of cables must be electrically bonded past the manhole boxes and connected to the rails at the nearest point to the power station.

ABSTRACT OF BOARD OF TRADE MEMORANDUM, REGARDING DETAILS OF CONSTRUCTION AND EQUIPMENT FOR TRAMWAYS AND LIGHT RAILWAYS LAID ON PUBLIC ROADS.*

Clearance.

There should be at least 15 ins. between the sides of passing cars and also a similar space between the side of a car and any standing work, such as lamp, telegraph and trolley wire posts in a street.

There should be at least 15 ins. between the side of a car and the kerb, whether on straight or curved roads.

The clearance between the top deck of cars and the underside of bridges should not, if possible, be less than 6 ft. 6 ins. Where this clearance cannot be obtained special precautions in working will be required, but in no case will less than 6 ft. be accepted with uncovered cars.

Posts and Brackets.

Where bracket arms 16 ft. in length will not suffice, it is desirable that span wire construction should be used.

The overhead conductors used in connection with the working of the tramways should be securely attached to supports, the intervals between which should not, except with the approval of the Board of Trade, exceed 120 ft., and the overhead conductors should be in no part at a less height from the surface of the street than 20 ft., except where they pass under bridges.

The overhead conductors should be divided up into sections not exceeding (except with the special approval of the Board of Trade) one-half of a mile in length, between every two of which should be inserted an emergency switch so enclosed as to be inaccessible to pedestrians.

Poles supporting gas lamp brackets should be efficiently bonded to the rails.

Permanent Way.

The weight of rails should not be less than 90 lbs. per yard, 100 lbs. being preferred.

The groove of the rail should not exceed 1⅛ in. in width, but a groove not exceeding 1¼ in. will be accepted on curves of less than 150 ft. radius.

Cars.

Of existing types of lifeguard, the 'trigger' is the pattern which is preferred. The hanging gate should be as close to the ground as possible, and there should be at least 3 ft. between it and the front of the guard. Both the guard and the gate should be at least as wide as the outside of the frame of the truck. The tray of the guard should be provided with a spring so as to hold the front edge down to the surface of the roadway when the tray is dropped.

All railings should be connected with earth.

All electrical conductors fixed upon the cars in connection with the trolley wheel should be formed of flexible cables protected by indiarubber insulation of the highest quality and additionally protected wherever they are adjacent to any metal so as to avoid risk of the metal becoming charged.

The trolley standard of every double-deck car should be electrically connected to the wheels of the car in such manner as either to prevent the possibility of the standard becoming electrically charged from any defect in the conductors contained within it or in the event of the standard becoming electrically charged to give a distinctive and continuous warning signal to the driver or conductor. The signal may be a red lamp bridged with a suitable fuse or (preferably) an audible signal. The signal device should be tested at least once a week.

In the Board of Trade Memorandum dealing with guard wires on electric tramways the following regulations are laid down :—

Each guard wire must be well earthed at one point at least, and at intervals of not more than five spans. The resistance to earth must be such that a short circuit between a guard wire and a trolley wire will open the circuit breaker.

The earth connection should be made by connecting the support to the rails by means of a copper bond. When first erected, the resistance to earth of the guard wires should be tested, and periodical tests should be made to prove that the earth connection is efficient.

* The functions of the Board of Trade are now exercised by the Ministry of Transport.

Guard wires should be, in general, of galvanised steel, but in manufacturing districts in which such wires are liable to corrosion bronze or hard drawn copper wires should be used.

The gauge of the guard wire must be such that it will carry, without fusing, a current 50 per cent. greater than that required to open the circuit breaker, and the guard wire must be maintained in such a manner that it will at all times meet these requirements.

The supports for the guard wires should be rigid and of sufficient strength for their purpose, and at each support each guard wire must be securely bound in or terminated.

The rise of the trolley boom should be so limited that if the trolley leaves the wire it will not foul the guard wires.

A Summary of the Board of Trade Regulations for Electric Tramways.

The following is a brief summary of the principal regulations affecting electric traction :—

When any rails on which cars run, or any conductors laid between or within 3 feet of such rails, form any part of a return, such part may be uninsulated. All other returns, or part of a return, shall be insulated, unless of such sectional area as will reduce the difference of potential between the ends of the uninsulated portion of the return below 7 volts.

Where any uninsulated conductor laid between or within 3 feet of the rails forms any part of a return, it shall be electrically connected to the rails, at distances apart not exceeding 100 feet, by means of copper strips having a sectional area of at least $\frac{1}{10}$ of a square inch, or by other means of equal conductivity.

All uninsulated returns shall be connected to the negative pole of the generator; the negative terminal of the generator shall be also connected through a current-indicator, mentioned below, to two separate earth connections, which shall be placed not less than 20 yards apart. This clause enacts that the two earth connections may be replaced by making one connection to a water-pipe of not less than 3 inches internal diameter, provided that permission be obtained from the owner of the water-pipe and the person supplying the water.

The earth connections referred to in this regulation shall be constructed, laid, and maintained so as to secure electrical contact with the general mass of earth, and so that an electro-motive force not exceeding 4 volts shall suffice to produce a current of at least 2 amperes from one earth connection to the other through the earth, and a test shall be made at least once in every month to ascertain whether this requirement is complied with.

When the return is partly or entirely uninsulated the company shall, in the construction and maintenance of the tramway, (*a*) so separate the uninsulated return from the general mass of earth and from any pipe in the vicinity, (*b*) so connect together the several lengths of the rails, (*c*) adopt such means for reducing the difference produced by the current between the potential of the uninsulated return at any one point and the potential of the uninsulated return at any other point, and (*d*) so maintain the efficiency of the earth connections specified in the preceding regulations as to fulfil the following conditions, viz. :—

(i.) That the current passing from the earth connections through the indicator to the generator shall not at any time exceed either 2 *amperes per mile of single tramway line or 5 per cent. of the total current output of the station.*

(ii.) That if at any time and at any place a test be made by connecting a galvanometer or other current indicator to the uninsulated return and to any pipe in the vicinity, it shall always be possible to reverse the direction of any current indicated by interposing a battery of three Leclanché cells, connected in series, if the direction of the current is from the return to the pipe, or by interposing one Leclanché cell if the direction of the current is from the pipe to the return.

In order to provide a continuous indication that the condition (i.) is complied with, the company shall place in a conspicuous position a suitable, properly connected, and correctly marked current indicator, and shall keep it connected during the whole time that the line is charged.

The owner of any such pipe may require the company to permit him at reasonable times and intervals to ascertain by test that the conditions specified (ii.) are complied with as regards his pipe.

When the return is partly or entirely uninsulated, *a continuous record shall be kept by the company of the difference of potential during the working of the tramway between the points of the uninsulated return furthest from and nearest to the generating station. If at any time such difference of potential exceeds the limit of 7 volts, the company shall take immediate steps to reduce it below that limit.*

The current density in the rails shall not exceed 9 amperes per square inch of the cross sectional area.

The insulation of the line and of the return when insulated, and of all feeders and other conductors, shall be so maintained that the leakage current shall not exceed one-hundredth of an ampere per mile of tramway. The leakage current shall be ascertained daily before or after the hours of running when the line is fully charged. If at any time it should be found that the leakage current exceeds *one-half* of an ampere per mile of tramway, the leak shall be localised and removed as soon as practicable, and the running of the cars shall be stopped unless the leak is *localized and removed within 24 hours.*

The insulation resistance of all continuously insulated cables used for lines, for insulated

returns, for feeders, or for other purposes, and laid below the surface of the ground, shall not be permitted to fall below the equivalent of 10 megohms for a length of one mile.

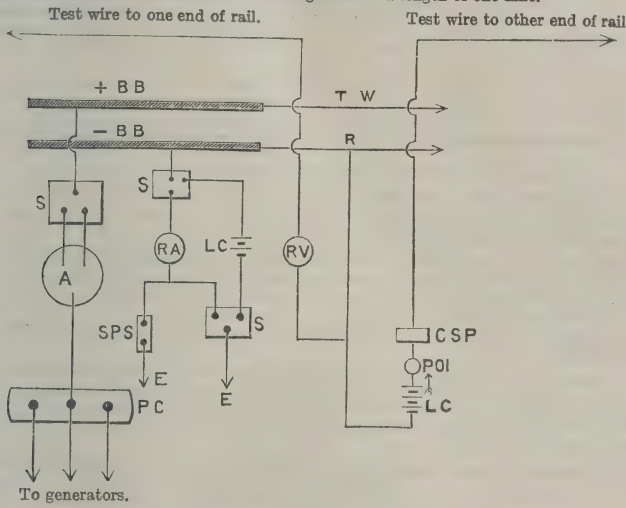

FIG. 13.—Diagram of Board of Trade Switchboard.

A, Ammeter reading $\frac{1}{10}$ – 3 and $\frac{1}{2}$ – 10 as.; B B, Bus bars; R, Return; T W, Trolley wire; S, Two-way switches; R A, Recording Ammeter 2 to 25 as.; R V, Recording voltmeter 2 to 10 v.; L C, Leclanché cells; S P S, S.P. switch; E, Earth; P C, Three-way plug connections; P O I, P.O. indicator; C S P, Contact of sensitised paper.

Specification for Poles.

BRITISH STANDARD SPECIFICATION FOR TUBULAR TRAMWAY POLES.*
(No. 8—1904.) *(Abstract.)*

1. The poles shall be of mild steel free of all defects, and shall be of three classes—light pole, medium pole, and heavy pole.

2. The sectional poles shall be either solid-drawn or lap-welded wrought steel, free of all defects, made up in three sections, swaged together when hot so as to make a perfect joint. The lap-welded seams in the sections shall be set at an angle of 120° to each other. The taper poles shall be of wrought steel, free of all defects, rolled in one length and butt-welded the entire length. The butt-welding shall be carried out at an even temperature without overheating, and no pole shall show any signs of burning at the weld.

3. The overall length of poles of all classes shall be 31 ft.

4. The length of the telescope joint in the sectional poles shall be 18 ins.

5. The length of the sections shall be :—

Top section	8 ft. 6 ins.
Middle section	8 ft. 6 ins.
Bottom section	17 ft.

6. The outside diameters, in inches, of the three classes of both sectional and taper poles shall be :—

SECTIONAL POLES.

Class.	Top.	Middle.	Bottom.
Light	5¼ ins.	6½ ins.	7¼ ins.
Medium	6½ ins.	7½ ins.	8½ ins.
Heavy	7½ ins.	8½ ins.	9½ ins.

* By permission of the British Engineering Standards Association.

TAPER POLES.

Class.	Top.	Outside diameter 9 ft. 6 in. from base.
Light	4⅜ ins.	7½ ins.
Medium	5⅜ ins.	8½ ins.
Heavy	6⅜ ins.	9½ ins.

7. The thickness of metal in any pole shall not be less than ¼ in.

8. The completed poles shall be straight and true over their entire length to within ¼ in.

9. The section of any pole shall be as nearly circular as possible, not varying in diameter more than $\frac{1}{16}$ in. from the adopted standard.

10. Five per cent. of each class of sectional pole shall be subjected to the following drop test :—

The pole shall be dropped vertically, butt downwards, three times in succession, from a height of 6 ft., on to a hard wood block 6 ins. thick laid on a concrete foundation, without showing any signs of telescoping or loosening of joints.

11. Five per cent. of each class of both sectional and taper pole shall be subjected to the following bending tests :—

The pole shall, in each case, be rigidly supported for 6 ft. from the butt, and loaded, as a cantilever, 18 ins. from the top, the load being applied at right angles to the axis of the pole, which shall be fixed horizontally. Upon the application of the following loads in lbs., the temporary deflection and permanent set, measured at the point of application of the load, shall not exceed the figures stated in the tables.

Class of Pole.	Load in Lbs. for Temporary Deflection not exceeding 6 ins.	Load in Lbs. for Permanent Set not exceeding ½ in.
Light	750 lbs.	1,000 lbs.
Medium	1,250 lbs.	1,750 lbs.
Heavy	2,000 lbs.	2,500 lbs.

12. In the event of any pole of the above-mentioned 5 per cent. not fulfilling the test requirements, a further 5 per cent. shall be subjected to the tests enumerated above. Should any further failure occur, the whole parcel from which the poles have been selected shall be liable to rejection

13. The maker, at his own expense, and to the satisfaction of the engineer, shall provide all the necessary testing apparatus at his own works for carrying out the above-mentioned tests.

TABLE OF STANDARD TUBULAR POLES.

Total Length of Pole.	Length and Outside Diameter of three component Pipes.			Total Weight.	Free from Permanent Set at
Feet.	Feet. Inches.	Feet. Inches.	Feet. Inches.	Lbs.	Lbs.
29	16½ × 10	8 × 8	7½ × 7	1,503	4,500
30	17 × 10	8½ × 8	7½ × 7	1,552	4,400
31	17 × 10	9½ × 8	7½ × 7	1,593	4,200
28½	16 × 8	8 × 7	7¼ × 6	1,193	3,400
29½	16 × 8	9 × 7	7¼ × 6	1,224	3,200
30	17 × 8	8½ × 7	7¼ × 6	1,259	3,150
28½	16 × 7	8 × 6	7½ × 5	769	2,000
29½	16 × 7	9 × 6	7¼ × 5	991	2,000
30	17 × 7	8½ × 6	7 × 5	998	1,800
28½	16 × 6	8 × 5	7½ × 4	689	1,200
29½	16 × 6	9 × 5	7½ × 4	613	1,000

Working Results.

WORKING RESULTS OF SIXTY-FOUR TRAMWAYS UNDERTAKINGS IN THE U.K. (*Pre-war*).

Particulars.	Lowest.	Highest.	Average.
Capital expenses per mile single track (trolley)	£5,800	£23,900	£11,000 to £14,000
Total revenue per car mile	6·06*d.*	13·23*d.*	9*d.* to 11*d.*
Total working expenses per car mile	4·76*d.*	8·65*d.*	6*d.* to 7*d.*
Total working expenses exclusive of power	3·28*d.*	6·10*d.*	4*d.* to 5*d.*
Total working expenses per passenger	0·49*d.*	1·19*d.*	0·6*d.* to 0·8*d.*
Total working expenses in percentage of total revenue	48	94	60 to 70
Net revenue in percentage of capital expenditure	0·8	15·4	4 to 8
Revenue per car per annum	£855	£2,319	£1,200 to £1,700
Revenue per mile of single track	£778	£9,179	£1,500 to £3,000
Average fare per passenger	0·69*d.*	1·47*d.*	1·00*d.* to 1·25*d.*
Average fare per mile ride	0·35*d.*	1·07*d.*	0·7*d.* to 0·9*d.*
Passengers per car mile	5·4	13·4	7 to 12
Passengers per car per annum in thousands	194	451	250 to 350
Journeys per head of population	30	211	100 to 150
Miles per day per car	62	130	80 to 110
Units per car mile, four-wheel cars	0·98	2·09	1·0 to 1·8
Units per car mile, all bogie cars	1·60	2·10	—
Units per car mile, roughly one-half four-wheel and one-half bogie	1·43	2·24	1·5 to 1·9
Cost of energy per unit	0·38*d.*	2·13*d.*	1·2*d.* to 1·6*d.*
Average speed miles per hour	6·0	8·7	7 to 8

Electric Brakes.

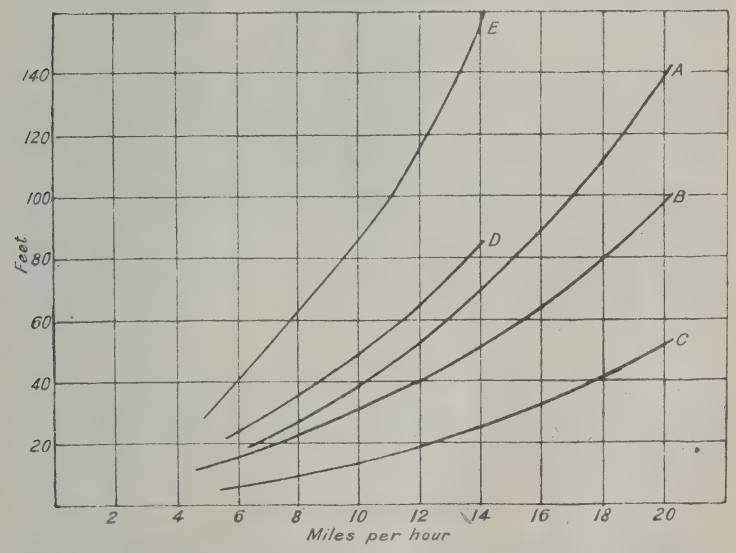

FIG. 14.

Fig. 14 shows the results obtained with tests on tramway cars fitted with various types

of electric brakes. Tests A, B, and C were made under the supervision of the Special Committee on Brakes of the Tramways and Light Railways Association, tests D and E were made by Mr. A. L. C. Fell. Tests A, B and C were made on a four-wheel car weighing 11 tons 9 cwt. loaded. Tests D and E were made on a bogie car weighing 13 tons with 6 persons. In every case the tests were made on a practically level track; in tests A, B, C, and D the rails were dry, in test E the rails were greasy. Tests A and E were made with a rheostatic brake, in tests B, C, and D the brake used was the Westinghouse electro-magnetic track brake, the track shoes being coupled to and acting with the ordinary brake shoes on the wheels. The results of each test are shown by a curve giving the speed in miles per hour at which the brakes were applied and the subsequent travel of the car in feet.

A comparison of curves D and B gives the relative effect of electro-magnetic track brakes acting under practically similar conditions on a bogie car and a four-wheel car. A comparison of curves A and B shows the behaviour of a four-wheel car under the action of a rheostatic brake and of a track brake in the case of ordinary service stops while curve C shows the effect of a track brake on a four-wheel car in an emergency stop. In all these cases the rails were perfectly clean and dry. Curve E shows what may take place with a heavy car on a flat but greasy rail when controlled only by a rheostatic brake.

Conduit Systems.

In the Conduit system the conductors conveying current to the cars are placed below the surface of the road in a specially constructed conduit. The car carries a plough which passes through a slot in the road and makes connection with the conductors beneath. In some cases, as in London, Washington, Paris and Bordeaux, the slot is placed midway between the two track rails, while in others, as in Berlin and Brussels, the slot is placed at the side and takes the place of the groove in the ordinary grooved tram rail. Some authorities object to the centre-slot on account of the amount of metal exposed in the street, and the consequent increased maintenance of the paving. Others object to the side-slot on account of difficulties connected with the switches, and of the fact that the wheel flanges tend to throw mud and water into the conduits.

Particulars of conduit tramways were given in previous editions of the YEAR-BOOK. Although retained in operation where it has been laid down, and extended when necessary, the conduit system is practically obsolete, and is too costly for adoption under modern conditions.

Railless Electric Traction.

Where the traffic conditions do not justify the construction of an electric tramway, but where electric power is available, railless traction provides an alternative to the motor omnibus. Two overhead conductors are provided, as lead and return, and the vehicles carry trolley poles with under-running trolleys collecting the current from the conductors. These trolleys permit the vehicle to deviate at least 15 ft. from the centre-line on either side, so that they can pass other vehicles; on meeting a similar vehicle moving in the opposite direction the trolleys of one must be removed from the conductors whilst the other passes. Railless tramcars compared with motor omnibuses have higher acceleration, lower working costs, longer life, and greater elasticity as regards the number of passengers carried, while they give a more reliable service and a greater annual mileage, and can climb hills with greater ease. The cost of maintenance is about 1*d.* per car mile (exclusive of tyre renewals, which amount to about 1*d.* also), and the consumption of energy is about 1 k.w.-hr. per car mile. The life of a trolley omnibus is ten to fifteen years, i.e., about double that of a motor omnibus. The vehicle costs about 2,000*l.*, and the overhead construction about 2,700*l.* a mile. The seating capacity of a single-deck car is 28, and the speed 16 miles per hour. Many installations of this class are at work in this country and abroad.

Industrial Electric Trucks.

For moving material about railway stations, factory premises, etc., electric battery trucks have been widely adopted, capable of carrying up to 5,000 lbs. and running at speeds up to 8 miles per hour; the net weight of the trucks is 1,600 to 2,500 lbs., and the mileage per charge 15 to 25 miles. In a railway warehouse 11 tractors and 600 trailers handled 130,000 tons per annum at an average cost of 15·1*d.* per ton. *(R. J. Mitchell.)*

Electric Battery Vehicles.

Electric battery vehicles are displacing horsed vehicles for the collection of refuse in cities, having proved much more economical. At Croydon the cost per ton with electric wagons was 9*s.* 4*d.*, and with horse-drawn wagons 11*s.* 10*d.*, and one of the former collected three times as much daily as one of the latter. The cost has been estimated as follows:—Cost of three 2-ton

electric vehicles, 4,000*l.*; cost of charging plant, 150*l.* The running expenses per annum, for a daily run of 25 miles, would be: Wages of nine men, 1,170*l.*; repairs and maintenance of chassis at 0·5*d.* per mile, 44*l.*; ditto of battery at 0·4*d.* per mile, 35*l.*; energy, 225 units per week at 1½*d.*, 61*l.*; tyres, at 1*d.* per mile per vehicle, 87*l.*; rent of garage, insurance, shoots, etc., 245*l.*; interest and sinking fund at 15 per cent., 622*l.*—total, 2,264*l.* per annum.

A railway company using several different types of electric parcel van finds that the total cost per mile is 4·3*d.*, on a basis of 10,000 miles per annum, with energy at 1*d.* per unit, tyres lasting 18,000 miles, and standing charges reckoned on a life of ten years for Edison batteries and two and a quarter years for lead batteries.

At Glasgow motor traction cost 4*s.* 6½*d.* per ton, horse traction 4*s.* 1½*d.* per ton, and electric traction 3*s.* 5½*d.* per ton.

Suitable speeds for commercial vehicles are as follows:—To carry 1,000 lbs., 12 to 13 miles per hour; 2,000 lbs., 10 to 11; 2 tons, 8 to 9; 4 to 6 tons, 6 to 7 miles per hour. The standard motors are wound for 80 volts for use with the lead battery, and for 60 volts for use with the alkaline battery. A 3-ton lorry will cover from 35 to 40 miles on one charge, and light passenger vehicles 70 or 80 miles. Comparative tests with horsed and petrol vehicles on parcel delivery rounds show that the electric vehicle effects a considerable saving in time, as well as in cost of energy for propulsion.

American experience shows that, during the first ten years of the life of an electric vehicle, it can be kept in service 280 days out of a possible 300 per year, and, if painting or disablement by serious accident is eliminated, 295 days out of 300. Over 70,000 electric vehicles are in use in the United States.

The "Orwell" Electric Battery Vehicles.

The main advantages of the electric propulsion of the 'Orwell' electric vehicles and the 'Orwell' electric industrial platform trucks are: simplicity of manipulation, efficiency of transmission of power to the wheels, silence, cleanliness, and low running costs. These vehicles are made by *Ransomes, Sims & Jefferies, Ltd.*, Ipswich, and are well suited for suburban and town work, where frequent stops are involved and busy thoroughfares have to be negotiated.

In the vehicles the type of transmission employed is, a drive from the rear wheels by motors bolted to each of the front swivel axles and driving the wheels by helical gears on the armature shafts which mesh with internal helical spur-rings on the wheel hubs, or a drive from the rear wheels by motors bolted to each side of the chassis frame amidships, and driving, through enclosed helical gears, independent countershafts that in turn transmit the power to the rear road wheels by roller chains. In this type of drive the transmission is very simple, owing to the fact that use is made of the electric differential action between the two motors, so that mechanical differential gear can be omitted. Furthermore, cardan and universal joints are dispensed with, and, lastly, a change-speed gear box is not required, the speed being controlled by the use of various electrical connections of the motor armatures and fields. Four speeds in the forward direction and one in the reverse direction are obtained by series-parallel connections of the armatures and by the use of series and shunt windings in various combinations.

The fact that the motors are provided with shunt windings renders it possible to make use of the regenerative action of the shunt type of motor, so that on hills the motors may be run as generators, thus acting as an effective brake to the vehicle, and at the same time recharging the batteries.

The controller effecting the necessary changes in connections of the motors is situated under the driver's seat. It consists of two interlocked drums carrying segments, upon which rest the contact-making fingers. The main drum is operated by a hand lever which can be put into any of the running positions, and the rheostatic drum is operated by a foot pedal and inserts resistance steps, and finally interrupts the current, as the pedal is depressed, the breaking of the current without arcing being achieved by the action of a magnetic blow-out. The interlocking of the drums is such that the hand lever can only be moved from one position to another when the foot pedal is depressed and the current is interrupted, and by this means it is impossible for sparking to occur on the main drum.

The foot pedal is used just as a clutch on a petrol vehicle, and by depressing and releasing it as obstacles present themselves or are removed from the road, the vehicle may be driven for long stretches without the necessity arising for using the change-speed hand lever.

The 'Orwell' vehicles are fitted with powerful hand and foot brakes, and these, together with the electric braking above referred to, provide a braking power sufficient for any emergency.

The range of action of the vehicles depends on the size of battery used and the nature of the roads to be traversed; on an average 25 to 45 miles may be run on one charge of the battery.

The number of units required to charge the battery is 30 to 35 units, so that at a cost of 1½*d.* a unit the battery may be completely charged for about 4*s.*, giving a cost of energy of about 1*d.* a mile.

The supply of current from the battery may be used to run auxiliary motors for tipping

the bodies or for actuating pumps, cranes or any auxiliary apparatus that may be required to add to the general utility of the vehicle.

The 'Orwell' electric industrial platform trucks are manufactured in many types in order to meet the great variety of services to which they can be put. They are intended to replace all types of hand trucks and wheel-barrows, and they have a large field of application in factories, on railway stations, and in all cases in which goods and materials have to be shifted for comparatively short distances in small bulk.

Two main types of 'Orwell' platform trucks are being manufactured, the type B truck with three wheels and the type C truck with four wheels. In the type B truck the battery is suspended on springs amidships and the single motor, fixed by a double-acting spring suspension to the underframe, drives the front wheel through a set of bevel gears working on to a layshaft fitted with a helical pinion engaging with an internal helical spur-ring attached to the wheel.

In the type C truck two of the wheels are used for driving, in a manner similar to that adopted in the front-wheel-driven electric vehicle described above, and the other pair of wheels are small rollers that enable the loading platform to be supported only 11 ins. from the ground, so as to facilitate the loading of heavy materials.

This 'C' type truck can be supplied with large trailing wheels, thereby giving a platform height intermediate between those of the two standard types, and an elevating platform can also be fitted if desired.

In both types two independent brakes are provided. The control is effected by a hand switch giving the direction of motion, and a foot pedal varying the amount of resistance in series with the motors, and thus adjusting the speed. The same pedal, when completely released, cuts off the current from the motors and at the same time applies the brakes.

The range of action is about 15 miles per charge with 3,000-lb. load, and the trucks are capable of ascending gradients of one in seven with this load. The trucks may also be used to drag loaded trailers. The small turning radius of 8 ft. for the type B truck, and 10 ft. for the type C truck, renders their use possible in congested workshops and tortuous passages.

The 'C' type truck can be supplied with four-wheel steering in lieu of two-wheel steering, in which case the turning radius is reduced from 10 ft. to 7 ft. 6 ins.

The cost of running an electric platform truck, including driver's wages, interest and depreciation, and current for charging, is about 200*l.* per annum, and as it is capable of displacing on an average about five workmen with hand barrows, it will be seen that the truck offers considerable economy.

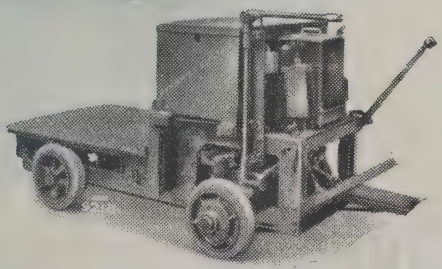
The latest type of 'Orwell' electric production is the Ransomes' Electric Runabout Crane Mossay-Ransome' system, which has been developed to fill the need for an expeditious, efficient, and mobile appliance to load, unload, and move about merchandise in docks, railway clearing-houses, warehouses, works and yards, and to supplement the working of the now familiar 'Orwell' Electric Platform Trucks.

It consists of a crane jib provided with lifting and luffing mechanism mounted on a turntable provided with steering and power road wheels, capable of imparting at will to the whole appliance forward, reverse, and rotary movements.

The 'Orwell' electric vehicles and platform trucks are driven by the 'Exide-Ironclad' type of lead battery, which type has gained a high reputation in U.S.A., as well as in this country. The standard number of cells in each battery is forty. The capacities usually are as follows:—For 20–30 cwt., 40–50 cwt. and 3½-ton vehicles, 193, 226 and 258 ampere-hours respectively, and for industrial platform trucks 129 ampere-hours, at the five-hour rate of discharge.

The positive plates used in the 'Exide-Ironclad' battery are radically different from the flat plates usually employed. Each consists of a number of vertical pencils joined at the top and bottom to horizontal bars. Each pencil contains a core of antimonial lead, which is surrounded by the active material, peroxide of lead, which, in turn, is enclosed by an ebonite tube having a large number of horizontal slits. These slits allow the electrolyte (dilute sulphuric acid) access to the active material.

Each ebonite tube is provided with two vertical ribs projecting on opposite sides at right angles to the face of the plate, which serve not only to stiffen the tubes, but also act as insulating spacers, taking the place of the ribs on the wood separators used in the 'Exide' batteries, and allowing the use of a plain wood diaphragm. The ebonite tubes have a certain amount of elasticity, allowing them to compensate for changes in volume of the active material, due to expansion and contraction during charge and discharge. The cylindrical form of tube is peculiarly well adapted to perform its function, since no amount of expansion or contraction will tend to alter its shape and the internal strains are thus kept uniform. Another advantage is that most of the necessary electrolyte is carried within the confines of the plate itself. The negative plate used with the 'Exide-Ironclad' positive is of standard 'Exide' flat type, but is thicker than is usually employed.



The positive and negative plates are separated from one another by means of veneers of wood. The containers are of ebonite, and the cells being completely sealed in, there is little danger of leakage of the electrolyte. As the containers are not of metal, it is unnecessary to keep them apart or to place any special insulating material between them. The cells are usually made up in lots of twenty, these being fitted in an iron-bound wood tray. The tray is fitted with

rollers so that one man can easily withdraw it for the purpose of inspecting and topping-up the cells.

The battery can be charged quickly and at any current rate that is obtainable, provided that the voltage per cell does not exceed 2·3, and the temperature is kept below 110° F. Its watt-hour and ampere-hour efficiencies are high. The internal resistance being very low, heavy currents, such as are called for when the vehicles are negotiating steep gradients, do not cause the voltage to fall very much, and so a good speed is maintained. The cost of charging the battery is low, as the efficiency is high. The capacity of the battery is not appreciably affected by the lowest temperatures experienced in this country. The manufacturers of the battery, the *Chloride Electrical Storage Co. Ltd.*, Clifton Junction, nr. Manchester, give a two-year guarantee with each battery, provided it is operated in accordance with their printed instructions, and subject to certain records being sent to them regularly. Two years must not, however, be taken as the maximum life of the battery; many that have been heavily worked have been in commission over three years and are still giving useful service.

Petrol-Electric Lorries.

In the petrol-electric vehicle the motive power is provided by a petrol engine, but the mechanical gear and clutch are replaced by a very flexible electric transmission. In a recent type of Stevens petrol-electric lorry of 3 tons capacity, the generator driven by the engine gives from 300 amperes at 80 volts to 230 amperes at 110 volts, and in addition to driving the vehicle it can be used to supply power for charging a battery or electric lighting, welding, etc. The electric motor is supplied through a special controller which gives forward and reverse connections with a wide range of speed variation, and when put in the neutral position enables the generator to supply electricity for external use. In the last case the generator can be given any desired characteristic—under, level, or over-compounded. A 3-ton wagon can supply three arc-welding equipments at 60 volts.

STANDING ORDERS OF THE HOUSE OF COMMONS WITH REFERENCE TO TRAMWAY BILLS.

The following are the principal Orders relating directly to tramroads and tramways.

Estimate.

This is the same as in the case of Railways (see page 663).

Plans.

In cases of Bills for laying down a tramway, the plans shall indicate whether it is proposed to lay such tramway along the centre of any street, and if not along the centre, then on which side of, and at what distance from, an imaginary line drawn along the centre of such street; and whether or not, and if so, at what point or points it is proposed to lay such tramway, so that for a distance of 30 feet or upwards a less space than 9 feet 6 inches, or if it is intended to run thereon carriages or trucks adapted for use upon railways a less space than 10 feet 6 inches, shall intervene between the outside of the footpath on each side of the road and the nearest rail of the tramway.

All lengths shall be stated on the plan and section in miles, furlongs, chains, and decimals of a chain. The distances in miles and furlongs from one of the termini of each tramway shall be marked on the plan and section. Each double portion of tramway, whether a passing-place or otherwise, shall be indicated by a double line. The total length of the road upon which each tramway is to be laid shall be stated (*i.e.* the length of route of each tramway).

The length of each double and single portion of such tramway and the total length of such double and single portions respectively shall also be stated.

In the case of double lines (including passing-places), the distance between the centre lines of each line of tramway shall be marked on the plans. This distance must in all cases be sufficient to leave at least 15 inches between the sides of the widest carriages and engines to be used on the tramways when passing one another. The gradients of the road on which each tramway is to be laid shall be marked on the section. Every crossing of a railway, tramway, river, or canal shall be shown, specifying in the case of railways and tramways whether they are crossed over, under, or on the level.

All tidal waters shall be coloured blue.

All places where for a distance of 30 feet and upwards there will be a less space than 9 feet 6 inches between the outside of the footpath on each side of the road and the nearest rail of the tramway shall be indicated by a thick dotted line on the plans on the side or sides of the line of tramway where such narrow places occur, as well as noted on the plans, and the width of the road at those places should also be marked on the plans.

ROADS AND STREETS.

ADMINISTRATION.

Road administration in the United Kingdom is carried out by individual local authorities, each of which appoints its own road surveyor. The financial arrangements are, however, such as to lead to relations between the council of a county and those of districts in the same administrative county, as regards some proportion of the roads, the extent to which this has occurred depending partly upon the circumstances of the area and partly upon the policy of the councils concerned.

The Road Board.

(Now absorbed in the Roads Department of the Ministry of Transport.)

The chairman of the Road Board is also the director, or chief executive officer of the Board. The secretary and the chief and assistant engineers are permanent officers, and the services of a consulting engineer are retained. The Board is assisted by an Engineering Advisory Committee, in which several county surveyors are included. Ample powers to acquire land for the making of new roads and for road improvements have been conferred upon the Board, by the Development and Road Improvement Funds Act of 1909, under which it was constituted. The work of the Road Board consists primarily in the allotting of grants to local authorities for the purpose of road improvement. In addition, the Board issues circulars and specifications indicating the policy and methods which should be followed in making such improvements, and has begun the work of compiling statistics and conducting experimental research.

The income of the Road Development Fund in the year 1911–1912 was a little over a million sterling, nearly 592,000*l.* of the total being derived from motor spirit duties and about 403,000*l.* from carriage license duties. The grants actually made amounted to nearly 410,000*l.*, and the loans to about 25,000*l.* Further large grants were 'indicated.' Up to March 31, 1912, about four-fifths of the total of the sums allotted was for the improvement of road crusts. In making grants towards the cost of an improvement the Board usually makes it a condition that the local authority shall pay a part, sometimes the larger part, of the cost; but each case is considered on its merits and the Board sometimes pays a large proportion of the total cost of the improvement. The Board is therefore able to exert a considerable influence in highway matters, though it has no administrative control of the councils or their surveyors. The income of the Board in 1912–1913 was nearly 1,253,000*l.*, of which about 702,000*l.* was from motor spirit duties, and 494,000*l.* from carriage license duties. The total of grants and loans made up to June 30, 1913, was nearly 1,475,000*l.*

Highway Authorities.

In all three Kingdoms the county councils are concerned with the maintenance of roads, but the arrangements differ, since there are no district councils in Scotland, while the relations between the county councils and the district councils are not the same in Ireland as they are in England and Wales.

England and Wales.—With some exceptions, applying to only a small mileage, the roads are maintained by the various authorities as follows. In cities and county boroughs all the public roads are maintained by the corporation or the borough council. In non-county boroughs and urban districts the urban council usually maintains all the roads, but the county council pays a considerable part of the cost of maintenance of such 'main' roads as pass through the area in question; and sometimes they are directly maintained by the county. With respect to rural roads it may be regarded as the normal arrangement for the more important roads, having been declared to be 'main' roads, to be maintained directly by the county council, and to be in charge of the county surveyor, while the other roads are maintained by the district councils, each council having its own surveyor. In effect there are wide differences, for the proportion of county roads to the whole may be very small or very large, the average being about 20 per cent.,

In other cases the 'main' roads are maintained by the district councils under a contract with the county council; or the most important of the district roads are the subject of grants made by the county council. Since the roads directly maintained by the county must be technically 'main' roads, it follows that in counties having a large proportion of the total mileage under county management many technically 'main' roads are roads which are in fact 'secondary' in character or even less important; and conversely, there are many counties in which the main roads in fact are classed as 'assisted roads,' or are, some of them, district roads maintained at the cost of the local ratepayers.

Ireland.—The roads in Ireland are divided into 'main roads' and 'district roads.' The latter are maintained by, and at the cost of the urban and rural districts in which they are situated, while the cost of main roads is equally divided between the district and the county. The sums for the maintenance of both classes of roads have first to be voted by the district councils, the power of the county council being almost entirely one of veto.

In 1911, about eighteen out of the thirty-three counties had no main roads, and the other fifteen had some a very large and others a very small mileage of main roads. Most Irish roads are maintained by contract, the contractors being usually small farmers, and the number of separate contracts very large, but the system is being replaced by the 'direct labour' system. Out of thirty-eight counties, 'ridings,' and county boroughs, this system was fully in operation in five, partly in fourteen (sixty-four out of ninety-seven rural districts), and not at all in nineteen, in the year 1911.

Scotland.—In Scotland there are no rural district councils. The urban roads within the burghs are maintained by the burgh councils and the rest of the roads by the county councils. Small counties, such as Elgin, Clackmannan, and Kinross, are each in charge of one surveyor, and Sutherland, where many of the roads are maintained by contract, has one surveyor. The larger counties are divided into districts, each in charge of a surveyor working under the district committee of the county council. Most of the counties are divided into two or three districts, but some large counties, such as Ayr, Perthshire, and Lanarkshire, into five. The mileage in a district ranges from about 120 miles in populous districts to some 500 or 600 miles in sparsely peopled districts. Each district committee of a county is composed of the county councillors representing that district. With their own officials they do all the county work for the district, and report their proceedings once a year to the county council, of which they are the component parts. In road matters the district councillors also report to the county road board which is composed of members from each of the districts. It is recognised that the roads are better managed by persons intimately acquainted with the needs and resources of the relatively small area, and it is held that it is better to secure the services of qualified and experienced men for the direct management of the roads in each district than to employ less efficient local surveyors under a county surveyor. One of the most telling criticisms of the English system is that district councils cannot pay adequate salaries to their road surveyors. Midlothian is an exception to the rule in Scotland, the system of management resembling that of an English county in which a large proportion of the roads are directly maintained by the county. There are four districts, each in charge of a district surveyor, the whole being controlled by a county surveyor, through whom the reports from each district are made to the county road board. The traffic in this area is considerable and of a severe character.

Recent Developments.

The most important of recent developments is the creation of the Ministry of Transport. In taking this step the Government officially recognises 'interests concerned.' This is a very important matter, because, up till now, the control of roads has been entirely in the hands of local authorities, and, to a small extent, of the Road Board.

Heavy motor passenger vehicles.—Some general provision by which heavy passenger vehicles such as the char-a-bancs which are domiciled in seaside resorts, and town omnibuses running out on to country roads, may be made to contribute directly to the cost of road maintenance will probably be made in the near future.

Closing certain roads to certain classes of vehicles.—It may also be expected that steps will be taken in the near future to schedule selected roads of a light class, such roads being available for certain types of heavy vehicles only when the vehicle is actually proceeding to a place which cannot be reached from other roads. This is quite a practical proposal, as what is desired is, not to harry the driver who chances to use such roads, but rather to be able to prevent regular services of heavy vehicles, pleasure or industrial, from being run on roads which are quite unsuited to, and are not necessary for, such traffic. See note after Table X, page 716.

Direct taxation.—There is a strong feeling in favour of the direct taxation of all who use the roads for profit, and all who wear the roads in the course of pleasure journeys, leaving all roads, as heretofore, free to the humblest users, and relieving the local ratepayer of a part of his burden. The principle of spreading the cost is already recognised in Road Board contributions for 'improvements.'

The Ministry of Transport.

The Ways and Communications Bill of 1919 became the Ministry of Transport Act, a change of title not without significance. Highways policy and administration are included in the jurisdiction of the new Ministry. On dates to be fixed by Orders in Council (these notes being written in November 1919) there are to be transferred to the Ministry all powers and duties of any Government Department in relation to : (*a*) Railways ; (*b*) Light Railways ; (*c*) Tramways ; (*d*) Canals, Waterways, and Inland Navigations ; (*e*) Roads, Bridges, Ferries, and vehicles and traffic thereon ; (*f*) Harbours, Docks, and Piers.

There is provision for the temporary transfer of 'undertakings' to the Minister for a period of two years ; any rates, fares, tolls, etc., fixed by him during that period to be in force for eighteen months after the expiry of the two years.

Tramways and Light Railways.—It is provided that if any tramway, or light railway used as a tramway by a local authority, of which the Minister takes possession, is liable, under any Act of Parliament or order to be purchased by a local authority, the Minister shall, when such purchase is complete, cease possession thereof. The Minister has the power to require through running and to settle the terms of such through running.

Roads Committee.—The constitution of a Statutory Committee for Roads, to some extent, meets the views of those who think that the administration of highways and the development of roads and road traffic should not be entangled with nor unduly influenced by other transport matters. It is doubtless important that all transport matters should be considered in their relations to one another, but it is also of the greatest importance to recognise the fact that the highway system of the country is complete in itself, unlike some other 'communications.'

The members of the Roads Committee will be appointed only after consultation with the Authorities and interests concerned. The scope of the Committee's operations is not limited to matters referred to them by the Minister ; they may regulate their own procedure and meet as often as they please. It may probably be assumed that the Statutory Committee will include among its members persons representing (1) the local authorities, (2) associations of users of motor vehicles, (3) farming interests, and (4) independent technical judgment.

The Road Department.—The Act also provides that the Ministry shall establish a separate Road Department 'charged with dealing in the ordinary course of departmental business with road construction, improvement, maintenance, and development.'

Revenue.—It is understood that the proceeds of motor taxation, the original tax or its equivalent, will be applied to their original purpose, in the financial year 1920–1921. In the 1919–1920 estimate ten millions was allotted for road purposes out of the general revenue. By July 1919, grants up to nearly eight millions had been arranged for 54 English and Welsh counties, 57 county boroughs, 27 Metropolitan boroughs, and 25 Scottish counties. In accordance with previous procedure highway authorities submit a statement showing that they are arranging (i) to execute out of their own resources at least as large a programme of road work as they carried out in the year ended March 1914, or, in special cases, the average of the three years ended March 1914 ; having regard to the increase in the cost of road work, and (ii) are also making the maximum practicable provision for dealing with works of deferred maintenance. Most authorities are proposing to add from one-third to one-half, and in some cases considerably more, to their highway expenditure of 1913–1914.

LEGAL POINTS FOR ROAD ENGINEERS.

The same principles of law govern all highways, whether carriage roads, bridle paths, or footpaths. The widths of some roads have been fixed by legal enactments; in England, for instance, by awards under Inclosure Acts, and in Scotland a minimum width, with powers to take a further width, was prescribed by the Roads and Bridges Act of 1878. The width of a highway may be greater than that set out in an award, but *prima facie* it is not. The width has often been determined by dedication, and in some cases the dedication was recent and the intended width may be clearly inferred; but in many cases the act of dedication is presumed, or the road is a legacy from ancient times. In such cases the usual presumptions are that the abutting owner of the soil is the owner of the soil to the middle line of the road, and that the right of public passage extends from fence to fence. Road engineers should note, however—when roads require widening—that there may have been recent encroachment and that a strip beyond the fence may be really a part of the highway. There have been many such encroachments. The principle 'once a highway always a highway' should not be lost sight of. The actual width of the highway and the nature and extent of the facility to which the public has a right may depend upon the manner in which and the extent to which the public has used the road and its margins as well as upon the extent to which and the manner in which the owner of the soil or his tenant has exercised rights of ownership, or has done things which tend to show that the dedication of the road is subject to reservations. It is important to note that a wayside ditch, though usually a part of the highway, may be outside the highway, and, especially when a road has been set out under an award, it should not be too readily concluded that a ditch lying beyond the width of the strip awarded is a part of the highway. The highway usually extends to a depth such as may be necessary for the proper maintenance of the road and to a height required for the passage of laden vehicles. The obstructions permitted on a highway are those which are authorised by Acts of Parliament, such as telegraph posts placed by the Postmaster General, and pipes laid by water and gas companies in defined areas. No individual or society has the right to place any post or other obstruction on the highway, except the owner of the soil where he can clearly establish a claim to such a right. Failing this, the presumption is that he cannot place on the highway anything which amounts to an obstruction of public passage in its widest interpretation. The highway authority may erect direction posts, and presumably, posts for cognate purposes, but it seems that such an authority may not erect lamp-posts unless they have powers as a lighting authority, even if the lamps are intended to facilitate the use of the road by the public. The highway authority has no powers enabling it to place posts or other obstructions upon the highway in the interests of certain classes of users of the road. The tendency is, however, for local authorities to go beyond their powers, and road surveyors will probably be required to carry out many works near the border line of those powers. Generally, as regards the placing of pipes, conduits, or wires along or across the highway, the persons doing so without statutory authority are likely to come into conflict with the public, or the owner of the soil, or both.

Width of Carriage-way.—There is usually a presumption that the highway is dedicated in part as a carriage-way, in part as footways, and grass margins which are regarded as occasional footways and rides, and in part as ditches, banks, and other enduring features necessary to the maintenance of the highway as established by use. It may, therefore, be desirable in some cases to obtain the formal consent of the owner of the soil to any radical alterations, such as the filling in of ditches. As regards trees and hedges it is important to distinguish between the powers of the highway authority as regards actual obstruction, and their further powers relating to the lopping of trees and cutting of hedges which injuriously affect the road.

Use and Abuse of the Highway.—In essence, the public right over the highway is one of passage along it only, and, although this principle is largely stretched by custom it is not broken, and those who stretch it unduly may be caught on the rebound, whether their acts result in injury or annoyance to the owner of the soil or his tenant, or, on the other hand, result in obstruction of or injury to the highway. Horses must be trained and exercised and motor vehicles tested for practical use upon the roads: but not to an extent or in a manner which amounts to obstruction or results in damage to the road. In this connection it may be noted that injuries to the road not coming under the head 'extraordinary traffic' may sometimes be dealt with as 'wilful damage.'

The relations of the three parties concerned may be briefly indicated as follows:—

The Highway Authority.—Must maintain the road in a condition fit for the passage of the public; may enforce the lopping of trees and cutting of hedges in the manner already indicated; may recover damages for substantial injuries caused by 'extraordinary traffic'; may enforce the removal of obstructions from the highway; may enforce by-laws such as those regulating the locking of wheels and the use of skidpans, and the widths of tyres in proportion to the loads carried.

The Public.—The public rights affecting the maintenance of roads include: the recovery of damages caused by 'misfeasance' on the part of the local authority, such as the placing of heaps of stone within the limits of the highway or the fixing of manholes, in such a manner as to cause accidents.

Any member of the public who finds on a highway an object which is in fact an obstruction or a nuisance may take proceedings against the person responsible for its presence, unless it is placed there under statutory authority.

Ownership.—In certain cases the highway authority becomes owner of the soil to a greater or less extent. In boroughs and urban districts, streets taken over by the local authority are vested in that authority. In rural districts 'a main road and the materials thereof and all drains belonging thereto' vest in the county council, but this does not constitute the council owners of the soil or give them powers over roadside wastes beyond those proper to their duties as the guardians of the public right of passage. As regards new roads made by the Road Board, the Board has the same powers and duties as those of a county council (except that of levying rates); and it is clear that if the road is on land which the Board has bought outright, with powers 'to sell, lease and manage' it, the Board becomes owner of the soil; and the Development Act does not seem to contemplate the acquisition by the Board of limited rights. In rural districts, highways other than main roads are vested in the owners of the soil.

Extraordinary Traffic.—The circumstances under which damages may be recovered for 'extraordinary traffic' cannot be shortly summarised, but the traffic may be extraordinary in amount, in character, or by reason of the manner in which it is conducted. Lord Justice Bowen has said 'extraordinary traffic is really a carriage of articles over the road at either one or more times which is so exceptional in the quality or quantity of articles carried or in the mode or time of user of the road as substantially to alter and increase the burden imposed by ordinary traffic on the road, and to cause damage and expense thereby beyond what is common.'

Heavy Vehicles on Bridges.—The owner of a bridge may prohibit the crossing of the bridge by a vehicle weighing more than 3 tons, but subject to confirmation, or an increase in the limit by an umpire or arbitrator.

HIGHWAY STATISTICS.

Road Mileage in Relation to Population and Area.

Road Mileage, per square mile.—Norway, 0·161; Spain, 0·174; Sweden, 0·205; New South Wales, 0·223; Hungary, 0·253; Switzerland, 0·465; Austria, 0·641; United States, 0·739; Scotland, 0·745; Italy, 0·834; Denmark, 1·724; Japan, 1·743; France, 1·750; Ireland, 1·755; England and Wales, 2·571.

Population per mile of road.—New South Wales, 24·6; United States, 41·8; Denmark, 75·5; Ireland, 77·13; France, 108·0; Norway, 115·4; Sweden, 154·4; Japan, 210; Scotland, 210; England and Wales, 239; Italy, 371; Austria, 385; Switzerland, 504; Spain, 575·8; Hungary, 655.

Approximate Mileages (1909).—The British Isles, 231,330: England and Wales, 151,000; Scotland, 24,800; Ireland, 55,560; England and Wales (1920), 152,000 miles.

Mileages in England and Wales (1909).—Rural, 118,642; urban, 32,000; urban roads outside London, 29,837; roads maintained by rural district councils, 95,077; rural roads maintained by or at the cost of county councils, 23,565; county borough roads, 9,366; roads in urban districts and non-county boroughs, 20,471; roads classed as 'main' roads, 27,754.

Mileages in Scotland (1909).—County councils (rural roads), 22,663; burgh councils, 2,108.

Costs per Mile of Road Maintenance.

England and Wales.

Annual Expenditures per Mile, all charges.—In 1906: The British Isles, 80*l.*; England and Wales, 88*l.*; Scotland, 51*l.*; Ireland, 22*l.*; Irish rural roads, 14*l.* In 1909: England and Wales, 89*l.*; Scotland, 48*l.*; Ireland, 19*l.* 10*s.*; Scottish counties, 31*l.*

Annual Costs of Maintenance only, per Mile (1909).—Main roads, urban, 206*l.*; county borough roads, 136*l.*; all roads in urban districts and non-county boroughs, 112*l.*; London, 335*l.*; rural roads maintained by or at the cost of county councils, 75*l.*; rural district roads, 23*l.*; urban roads generally, 134*l.*; rural roads generally, 33*l.*; 'main roads' 95*l.*; all English roads and streets, 54*l.* For 1910:—Main roads, urban, 210*l.*; county borough roads, 136*l.*; London, 333*l.*; rural roads maintained by or at the cost of county councils, 79*l.* Rural district roads, 23*l.* Total rural, 34*l.* All English roads and streets, 54*l.*

(1910-1911.)

Main roads, urban, 220*l.*; county borough roads, 137*l.*; London, 336*l.*; rural roads maintained by or at the cost of county councils, 86*l.*; rural district roads, 24*l.* Total rural, 37*l.* All roads and streets, 58*l.*

(1912-1913.)

County Main Roads.—Northamptonshire, 319 miles, 80*l.*, maintenance only; Cumberland, 460 miles, 66*l.*; Essex, rural roads, 619½ miles, 168*l.*, including minor improvements; Essex, urban roads maintained directly by the county, 61½ miles, 410*l.*

Other roads.—Essex, main roads maintained by urban authorities at cost of county, 119½ miles, 424*l.*, excluding improvements. Cumberland, main roads maintained by urban authorities at cost of county, 73 miles, 95*l.* Isle of Wight, main roads, 232 miles, 63*l.*; and district roads, 86 miles, 10*l.* 9*s.* 8*d.*, ordinary maintenance.

Mileages in 1913–1914.—England and Wales: Metropolitan Boroughs, 2,168; County Boroughs, 10,304; Non-county Boroughs, main roads, 1,264; other roads, 4,867; Urban District Councils, main roads, 2,358, other roads, 11,871; Counties, main roads, 19,588 (English Counties, 16,831; Welsh Counties, 2,757); Rural Districts, main roads, 4,989; other roads, 94,628. The figures for 1919–1920 are substantially the same, but the local costs of maintenance have been so much and so differently affected by the war, that the 1913–1914 figures have been used for the tables given in succeeding pages, as forming the best basis for comparison with future returns.

Costs of Maintenance and Other Expenditure.

Comparative Tables.

(Compiled from the 'Local Taxation Returns, 1913–1914.)

In the following tables the populations and assessable values of the different areas are given in those cases in which they have an important bearing on the costs of maintenance. Since, in any county, the roads classed as main roads are usually the more important, and those classed as district roads the less important, it follows that the cost of maintenance per mile of main roads is to some extent inversely proportional to the mileage of main roads as against the total road mileage in the county. The work of collecting traffic statistics was interrupted by the war, but will be taken into consideration in future tables.

Table I.—Roads and Streets: Metropolitan Boroughs, 1913–1914.

Maintenance and Repair, and Scavenging.

Name of Borough.	Mileage of Roads and Streets Maintained.	Cost per mile: Maintenance and Repair.	Cost per mile Cleansing and Watering.	Name of Borough.	Mileage of Roads and Streets Maintained.	Cost per mile: Maintenance and Repair.	Cost per mile Cleansing and Watering.

22	Burton-on-Trent	48,000	297,000	44	244	91	335
23	Chester	39,000	221,000	29	314	nil	314
24	Canterbury	25,000	131,000	35	199	33	232

Corresponding totals, all 78 county boroughs, (4) 10,304, (5) 247, (6) 92, (7) 339; ditto, maintenance and repair, (4) 10,304, (5) 150; ditto, corrected (4) 10,304, (5) 144.

NOTES ON TABLE II.

The average cost per mile for maintenance and repair is taken from the analysis of the total expenditure, thus: maintenance and repair, 150·2*l.*, improvements, 11·3*l.*, other items 85·5*l.*; total, 247*l.* per mile. The corrected figure of 144*l.* is obtained by taking certain financial adjustments into consideration, and the figure of 150*l.* per mile is probably more accurate for purposes of comparison. Expenditure out of loans was not applied to ordinary maintenance and repair.

Grouping of Boroughs.—Nos. 1 to 5 are seaport towns; 6 to 11, towns in large industrial areas; 12 to 14, health resorts; and 15 to 24, other county boroughs in different parts of England. In using the table, the analysis of the total expenditure from revenue may be taken as a rough guide to the probable apportionment in individual cases, and for this purpose sufficiently accurate proportions of the figures in column 5 are, maintenance and repair, $\frac{26}{43}$; improvements, $\frac{2}{43}$; other items, $\frac{15}{43}$.

TABLE III.—NON-COUNTY BOROUGHS: PUBLIC ROADS AND STREETS, 1913–1914.

29 Welsh Boroughs (included above)	—	212,000	855,000	82	399	481	—	—	—

NOTES ON TABLE III.

The total expenditure, out of revenue and out of loans, amounts to 239*l.* per mile, to the nearest £.

* *Aberystwith.*—The high figure, 305*l.* per mile, includes the cost of house scavenging, which is not separately reported by this borough.

Analysis.—The total expenditure of 239*l.* per mile is made up as follows: maintenance and repair, 146*l.*; improvements, 57*l.*; other payments, 36*l.*, bridges about 3*s.* per mile.

The item, 'other payments,' is not apportioned between main roads and other roads, but the remaining expenditure is as follows:—

Main roads.—Maintenance and repair, 261*l.*; improvements, 77*l.*; total, 338*l.* per mile.

Other roads.—Maintenance and repair, 116*l.*; improvements, 52*l.*; total 168*l.* per mile.

Wales.—The Welsh boroughs are included in the above totals. The separate figures for Wales are, for maintenance and repair, main roads, 133*l.*; other roads, 53*l.* per mile.

Road Board Grants amounted to 3,204*l.*

Receipts from County Councils amounted to about 28*6l.* per mile in respect of maintenance, repair and improvement of main roads, and a sum of nearly 31,000*l.* in respect of other highways and footpaths.

Bridges and ferries.—The boroughs expended about 36,000*l.* on bridges and ferries, in addition to the small sum included in road expenditure.

Cost per head.—The total expenditure on roads works out to about 6*s.* 7*d.* per head of the population.

NOTES ON TABLE IV.

For the sake of comparison the twenty-seven urban districts are in four groups. The 'A' group are districts situated in mountain or moorland areas; those of the 'B' group are coast or estuary towns; those of the 'C' group are in large industrial areas; and those of the 'D' group are selected from areas which differ much in character but are all farming areas, and these districts are not situated near large industrial areas. There are, in every group, enough districts of about the same population to provide comparisons between groups, and the range of populations in every group allows of another comparison.

Analysis.—The analysis shows that for the whole country (England and Wales) the expenditure on maintenance and repair on all roads is almost exactly four-fifths of the total expenditure out of revenue, the figures to the nearest £ being 141*l.* and 113*l.* per mile. This analysis is not made for individual urban districts (in the Local Taxation Returns) so that column 10 does not necessarily show the expenditure on maintenance and repair, but is given for the sake of comparison with the figure for the whole country.

Maintenance and repair.—The 2,358 miles of *main roads* cost about 233·6*l.* per mile; and the 11,871 miles of *other roads*, about 88·6*l.* per mile; *all roads*, average, 113*l.* per mile, Wales included.

Wales alone, main roads, 94·3*l.*; *other roads*, 88·4*l.* per mile.

Improvements.—Out of revenue, the expenditure on the improvement of *main roads* was 30·9*l.*, and *other roads*, 8·7*l.* per mile; average on all roads, 12·4*l.* per mile. Adding the last figure to the expenditure on 'street improvements,' 20·2*l.*, we get a total expenditure on improvements of nearly 32·6*l.* per mile.

Bridges.—Out of revenue, about 2·4*l.* per mile of main roads was spent on county bridges. The whole expenditure on all bridges was about 1·5*l.* per mile of all roads.

Payments by county councils in respect of main roads and bridges (maintenance, repair, and improvement) amounted to nearly 273*l.* per mile of main roads, and receipts from the Road Board to nearly 5·8*l.* per mile of all roads. Cost per head about 5*s.* 9*d.*

NOTES ON TABLE V.—OTHER TOTALS.

The mileages of roads in Tables III, IV and VI, do not always agree exactly with totals in Table V, a distinction being made in some cases between the mileage repairable and the mileage actually maintained. The method of accounting for some minor items is, moreover, not always the same. The following figures are, however, in substantial agreement with figures calculated from other returns.

Main Roads, English and Welsh Counties.—Expenditure out of loans, 15*l.*; total expenditure, 150*l.* per mile. England alone, total expenditure, 155*l.* per mile.

County Council Roads, directly maintained.—Urban, 744 miles, 280*l.* per mile; rural, 18,844 miles, 129*l.* per mile.

Main Roads maintained or County Councils.—Urban, 3,529 miles, 271*l.* per mile; rural, 4,947 miles, 106*l.* per mile.

All main roads, England and Wales, 28,064 miles, 147*l.* per mile; Wales (and Monmouth) 2,995 miles, 102*l.* per mile.

Bridges.—County expenditure on county bridges, per mile of county main roads, 12*l.*

Road Board Grants to counties, expressed as an average per mile of directly maintained roads, 25*l.*

Recent Costs per mile.—Expenditure during the war was affected by so many factors that comparisons are of little value. In most cases there are heavy arrears to be made up.

The following may be noted as examples: 1918–1919, Northamptonshire, 100*l.*; Essex, 183*l.*; estimate for 1919–1920, Gloucestershire, 82*l.* 1913–1914, Northamptonshire, 104*l.*; Essex, 229*l.*; Gloucestershire, 93*l.*, per mile.

NOTES ON TABLE VI.

In a few only of the fifteen counties in the table did the district councils spend any appreciable amount out of loans, the average for all rural districts in England and Wales being only about 2 per cent. of the expenditure out of revenue. The last entry, all counties, shows total expenditures on main and other roads on the same basis as the expenditures as stated for individual counties. The average extent to which these must be diminished in order to get figures for maintenance and repair only is shown by the totals as follows: *main roads*, entry for all counties, 98*l.*, or, more nearly, 98 4*l.*; expenditure for *maintenance* only, 95*l.* per mile. *Other roads*, entry for all counties, 28*l.*, or more nearly 27·6*l.*; expenditure for maintenance and repair only, 26·3*l.*

Improvements.—Expenditure on the improvement of *main roads* out of revenue was about 4*l.* per mile, and on other roads, out of revenue and loans, about 1·3*l.* per mile.

Other expenditure on roads, not included in table, nor in the above calculations: *salaries* of highway officers, less than 1*l.* per mile; *bridges*, less than four shillings per mile of roads (total mileage).

Unmetalled roads.—In the total of 94,628 miles of 'other' roads, there is included 2,813 miles of roads not paved nor metalled, or just over 3 per cent.

County Councils refunded about 103*l.* per mile in respect of main road maintenance and repair and about 3*l.* per mile in respect of main road improvement.

Wales and Monmouth.—The maintenance and repair of 31 miles of main roads in Welsh rural districts cost 76·9*l.* per mile, and of 13,058 miles of other roads, 14·2*l.* per mile.

The population of the 661 rural districts of England and Wales is about 7,733,000, and of the 78 rural districts in Wales and Monmouth about 808,000.

Indian Roads.—Since the expenditure upon the construction of Indian roads has in many cases been ample, usually adequate, and seldom recklessly parsimonious, and since, further, the work has been done by or under some control from the Royal Engineers or the Public Works Department, we cannot strictly compare the cost of their maintenance with maintenance costs of English roads, some of which have been made a little at a time and others developed from rough tracks, the average first costs being very low. An Indian province which presents a considerable variety of favourable and unfavourable conditions, the Madras Presidency, has, outside municipal areas, some 25,700 miles of roads, about 4,000 miles being unmetalled. The Public Works Department maintains some 700 miles, including important ghât roads, but including also about 400 miles of unmetalled roads, for the most part partially bridged and drained. The remaining 25,000 miles are maintained by the local boards. The Public Works Department metalled roads are very well maintained at a cost of about 20*l.* per mile, and the unmetalled roads at about 9*l.* per mile per annum. The local board roads cost about 10*l.* per mile.

Near Peshawar, unmetalled trans-frontier cart roads cost from 6*l.* 10*s.* to 12*l.* 10*s.* per mile. These are pre-war figures and may probably be doubled to represent present costs.

REGULATIONS FOR WHEELS AND LOADS.

Traction Engines.

A traction engine must have driving wheels with tyres not less than 2 ins. in width (each wheel) for every ton of its weight. Above 14 ins. the width may be reduced in proportion as the diameter of the wheels exceeds 5 ft. The maximum weight is 14 tons (or 16 tons fully equipped), for which 18-in. driving wheels are required with wheels 7 ft. 9 ins. diameter. Three trailers may be used, besides the water-cart. Trailers having cylindrical wheels, with springs, and with 9-in. tyres, may carry 9 tons 6 cwt. each. Borough and county councils may permit heavier loads than the above (locally), and single articles imposing greater weights may be carried, at the carrier's risk as regards recovery of damages caused by 'excessive weight.' Traction engine driving wheels must be 'cylindrical and smooth-soled, or shod with diagonal cross-bars of not less than three inches in width, nor more than three-quarters of an inch in thickness, extending the full breadth of the tyre, and the space intervening between each such cross-bar shall not exceed three inches.' This arrangement provides for almost the maximum amount of deadly effect upon the road with the minimum of advantage to the owner of the traction engine. Pending the repeal of this provision every effort should be made to induce owners of traction engines to provide their wheels with wooden strips, let in between, and flush with the diagonal cross-bars. On the average, such wheels would probably bite better than those with diagonal cross-bars only, and would tend to lessen the wear and tear of the engine itself, as well as to reduce the loss due to successful claims for damage done to roads by 'extraordinary traffic.' New engines should be provided with wheels having diagonal bars much closer together, an arrangement which does not seem to restrict the use of traction engines for road work—as distinct from field work—when such engines are registered as 'heavy motor cars.'

Heavy Motor Cars.

This term applies to motor vehicles weighing more than two tons unladen, and refers to three distinct classes: (1) Motor wagons or lorries; (2) traction engines not exceeding 5 tons in weight and in other respects fulfilling the requirements; and (3) delivery vans and omnibuses, provided with rubber tyres and allowed to travel at 12 miles an hour.

Maximum Weight, Heavy Motor Cars.—The vehicle unladen, 5 tons; vehicle and trailer, unladen, 6½ tons; 'axle-weight' (any pair of wheels with their full load), 8 tons; axle-weight of trailer, 4 tons.

Tyre Widths.—These are: minimum for the vehicle itself, 5 ins.; minimum for the trailer, 3 ins. All wheels: ½ in. for each 'unit of axle-weight,' which is, 7½ cwt. for a 3-ft. diameter wheel, 1 cwt. more for every 12 ins. more, and 1 cwt. less for every 6 ins. less diameter. These rules do not apply to wheels with rubber tyres.

The following table gives for each of the wheel diameters in the first column: the unit axle-weight proper to that diameter, the heaviest load, in each case, permitted on the minimum width of tyre, and the width of tyre required for the maximum axle-weight of 8 tons for the vehicle and 4 tons for the trailer. Intermediate values can easily be found.

TABLE VII.—GREATEST AND LEAST WEIGHTS AND TYRE WIDTHS UNDER THE HEAVY MOTOR-CAR ORDER, 1904.

5 6	10	5 0 8 0	3 0 4 0	5 8	3 4

Tyre Width, Camber, and Pressures.—The value of width of tyre in reducing the pressure of the wheel upon the road crust is not fully operative even on flat roads, since the wider the tyre the more frequent are the occasions on which it fails to bear for its full width on the slightly uneven surface of the road. The effect of width in reducing pressure has a more definite limit on hard roads with a sharp camber, unless the road is wide, with sloped and not barrelled camber, and the vehicle travels wholly to one side of the middle line. On a barrelled camber, the vehicle does not rest upon the full width of its tyres even when keeping to one side of the road. Traction-engines traversing narrow roads tend to wear them into a pair of parallel flat strips, with an exaggerated cambered part in the middle. Since the reduction of bearing width is a serious matter, and, apart from unusually troublesome vehicles and difficult roads, applies to many classes of vehicles on properly made roads, and even to tyres no wider than 3 ins. or 4 ins., it is necessary to take it into account in the development of vehicles and roads. In the first place it is desirable to find what is the average relation between diameter and tyre width as regards pressure, a relation which depends upon the modulus of elasticity of the crust and other factors. Since, however, wheels of large diameter punish the road less than wheels of small diameter, even when the actual pressures (load per sq. in. of surfaces in contact) are somewhat higher, the position generally may be no worse even if we fail for some time to establish the true relation and make the tyres of large diameter wheels somewhat too narrow. A general increase in the diameters of the wheels of many vehicles is, then, to be aimed at. The principle is recognised in the regulations for heavy motor cars. Next, as regards tyres which are necessarily very wide, attempts should be made to design the vehicles so that some duly constrained side play, angular or bodily, is permitted to the wheels. The side play which the wheelwright, with centuries of experience behind him, gives to cart and wagon wheels, greatly tends to economy in the wear and tear of the vehicles and the road, side play taking place to a large extent between the greased axle and the hubs of the wheels instead of occurring as a rubbing of the wheels on the road. The play is partly axial, but to a small extent angular, and allows of a slight adjustment to the cambered road. Thirdly, dead flats on roads (no gradient) should, as opportunity arises, be converted to gradients of 1 in 200, or steeper, and the camber reduced. On steeper gradients, and with some

road crusts and subsoils, a nearly flat camber is suitable, and in other cases a slight tilt to one side only may be given to the whole crust.

Tyre Widths for Horse-drawn Vehicles.—Under the Highways and Locomotives Amendment Act, 1878, a county authority may make regulations for tyre widths of vehicles drawn by animal power, in proportion to the loads carried. The following examples of such regulations are taken from 'The Surveyor and Municipal and County Engineer,' April 21, 1911.

TABLE VIII.—TYRE WIDTHS FOR CERTAIN LOADS—*Four-Wheeled Vehicles.*

Passenger vehicles are not allowed to draw trailers.

PROPOSED RESTRICTIONS.

In 1915 a Departmental Committee of the Local Government Board considered the subject of the weight, construction and speed of 'heavy motor cars' and 'road locomotives,' and the restriction of heavy traffic on unsuitable roads, and this is a matter which will doubtless be dealt with in the near future.

TABLE XI.—STEAM ROLLERS

The Rating of Motor Cars for Taxation.

AMENDED REGULATIONS (1913).

1. For the purposes of these regulations the horse-power of any motor car deriving its motive power wholly from an internal combustion engine worked by a cylinder or cylinders shall be taken to be :—

(*a*) In the case of a single-cylinder engine the horse-power attributable to the cylinder of the engine.

(*b*) In the case of an engine having two or more cylinders the sum of the horse-powers attributable to the separate cylinders.

2. The horse-power attributable to any cylinder of an internal combustion engine shall be deemed to be equal to the square of the internal diameter of such cylinder measured in inches divided by a numeral.

(*a*) In the case of a cylinder having a single piston, the numeral used as divisor shall be 2·5.

(*b*) In the case of a cylinder having two pistons, the numeral used as divisor shall be 1·6.

3. The horse-power of any motor car deriving its power wholly from a steam engine shall be taken to be proportional to the effective heating surface of the boiler supplying steam to such engine, at the rate of 1 h.-p. for every 3 sq. ft. in such effective heating surface, and the effective heating surface shall be taken to be :—

(*a*) In the case of a boiler having horizontal or approximately horizontal tubes, the whole of that surface of the tubes which is exposed to the flame or hot gases.

(*b*) In the case of a boiler having vertical or approximately vertical tubes, half of that surface of the tubes which is exposed to the flame or hot gases.

4. Any motor car deriving its motive power from an electric motor or motors shall be deemed to be of a horse-power exceeding 6½ but not exceeding 12.

5. In measuring cylinders and boilers, and in calculating horse-power, fractions of inches and feet and fractions of a unit of horse-power are to be taken into account.

6. Where it appears that in consequence of the exceptional design or construction of the engine of any motor car the horse-power as calculated under the preceding rules is substantially less than the average power which the engine would develop in continuous use on the road if there were no restrictions on speed other than those imposed by the car itself, then such average power shall be taken as the power of the car.

The Committee also suggest that motor cycles be taxed according to horse-power, and that the horse-power be determined as in the case of motor cars, a new class comprising cars of less than 5 h.-p. being added to the Schedule of Rates of Taxation in the Finance Act, 1900–10.

RESISTANCE TO TRACTION.

The results of traction experiments made by accepted authorities are collected and discussed in an appendix to the second edition of 'Road Making and Maintenance' (*Aitken*). Generally, the resistance to traction is much less with wheels of large diameter than with wheels of small diameter, and usually, taking good and bad roads and all kinds of weather, the tractive effort with wide tyres is considerably less than that with narrow tyres. With respect to the vehicles of many countries, and of some English counties, the word 'normal' might be substituted for 'narrow' in the above lines.

TABLE XII.—INFLUENCE OF DIAMETER OF WHEELS.

The following figures are taken from the results of experiments by General Morin:—

Pull in lbs. per 2,000 lbs., at 3 miles an Hour.

Nature of Road.	Cart without Springs. 4½-inch Tyres. Diameter of Wheels in Inches.		Wagon without Springs. 4½-inch Tyres. Diameters of Wheels in Inches.	
	64	80	36 and 60	44 and 78.
	Lbs.	Lbs.	Lbs.	Lbs.
Earth road, very good, nearly dry	55	44	74	63
Gravel road, loose gravel on firm earth	143	114	190	163
	168	134	225	192
	180	144	241	206
Broken stone road :—				
In good condition, dry	30	24	40	34
Firm, little soft mud	55	44	74	63
Portion worn out, thick mud	80	64	107	92
Stone block pavement, fair condition, dry	25	20	34	29
Thick oak bridge floor	35	28	47	40

Influence of Width of Tyres.

Under some circumstances narrow tyres offer less resistance to traction than wide tyres; but these circumstances are unusual, or in themselves undesirable, or do not hold in all kinds of weather. For instance, narrow tyres will cut through stiff mud on a hard bottom better than tyres which, though wider, are not wide enough to ride over the mud by pressing it in a rut of moderate depth. Wheels will run along ruts made by wheels with wider tyres but not in ruts made by narrower wheels. Narrow tyres will run through a layer of loose stones on a hard road better than wide tyres and they allow of the vehicle being pulled out of a slough which would hold down wider felloes. Generally, however, tyres classed as wide offer less resistance than tyres classed as narrow, and the more so when their cumulative effects on soft roads are considered, as well as the comparison of the moment. It is important to note that a vehicle which, on soft roads, can be pulled more easily than a similar vehicle with narrower tyres, will still show some advantage on a hard and firm road, or will not be at a disadvantage; and it must not be overlooked that in hot weather the tractive effort with narrow tyres is very high on asphalt pavements and even considerably increased on tarred roads.

The following are extracted from a table in which 1½-in. tyres and 6-in. tyres are compared the figures given being 'resistance to traction in lbs. per ton' (*Ira O. Baker*).

TABLE XIII.—INFLUENCE OF WIDTH OF TYRES.

Description of Road.	Width of Tyres. 1½-inch.	6-inch.
	Lbs.	Lbs.
Broken stone road, hard, smooth, no dust, no loose stones, nearly level	121	98
Gravel road, hard and smooth, few loose stones, size of black walnuts	182	134
Gravel road, new gravel, not compact, dry	330	260
Gravel road, wet, loose sand, 1 in. to 2½ ins. deep	246	254
Earth road, loam, dry, hard, no dust, no ruts, nearly level	149	109
Earth road, loam, stiff mud drying on top, spongy below	497	307
Earth road, clay, dry on top, but spongy below	618	464
Earth road, clay, stiff, deep mud	825	551
Earth road, loam, mud, 2½ ins. deep, very sticky, firm below	251	325
Earth road, clay, sloppy mud, 3 to 4 ins. deep, hard below	286	406
Earth road, loam, dry, loose dust, 2 ins. to 3 ins. deep	90	106

Tractive Effort on Different Pavements.

These experiments (*Ira O. Baker*) provide important comparisons between pavements differing only in condition as well as between pavements of different kinds. For instance, the pulls in lbs. per 2,000 lbs. were: on considerably worn wood blocks, 36; on asphalt at 42°F., 34; on oak plank, nearly new, 32; and on smoothly-dressed granite blocks, 30; but the 32 for oak plank rose to 38 when it had been worn down ¼ in. in many places; and the 34 for asphalt rose by 3 lbs. with a rise of 10° in temperature, and was 70 lbs. when the temperature was 84°F. On cedar blocks, a pull of 50 lbs. when they were covered with ¼ in. of crushed gravel, rose to 90 lbs. with a ½ in. covering of silica pea gravel. On a brick pavement, ½ in. of dust raised the pull from 17 lbs. to 31 lbs. On a steel plateway a pull of 19 lbs. was raised to 28 lbs. by ⅛ in. of fine dust, and to 40 lbs. by ⅛ in. of powdered stone. Out of a number of brick pavements the best required a pull of 17 lbs. per 2,000 lbs., and a granite macadam crust only 18 lbs.

Rubber and Iron Tyres.

Experiments made in 1895 showed that the tractive effort is less with pneumatic tyres than with solid rubber or iron, and that the advantage increases with increase of speed. Iron tyres were better than solid rubber on good or ordinary pavements, but required a somewhat greater pull on bad, irregular pavements.

Effect of Speed.—Experiments by Morin showed an increase of tractive effort with increase of speed. The differences between the pulls required at a walk and those at a fast trot were considerable, as were those between the pulls at a 'trot' and 'a fast trot.' Other experiments showed a very small increase with pneumatic tyres and much greater increases with solid rubber and with iron tyres. Since springs are generally used for the speedier and lighter vehicles comparisons between vehicles with springs and those without springs but of a similar character are not often made. It is difficult to say at what speed the provision of springs becomes an advantage as regards wear of the road, and this depends partly upon the diameter of the wheels and the width of tyres per unit load. Badly fixed springs may have a bad effect upon a road.

COUNTRY ROADS.

Widths of Roads.—The total width given to a new road should include provision for: (1) the carriage-way; (2) the supports for the edges of the crust, such as rough stone or gravel shoulders or 'water tables'; (3) such further strips of grass or other margin as may be necessary to hold drifted snow, to provide for the admission of air currents, or to keep sub-soil water at a suitable distance from the crust; (4) footways; (5) side ditches where necessary; (6) catch-water drains where necessary; (7) fences, and, where other parts of the width are not available, places for planting shade and shelter trees. The need for each of these or its relative importance depends upon climatic conditions, soil, the cost of land, and other circumstances. Some authorities give 30 ft. as the minimum width between fences and, generally, an ample width is desirable for economy of maintenance and efficiency.

Width of Carriageway.

Width of Carriageway.—This may be decided by the width needed for safe passing of vehicles, or that which with the materials available is the most economical. The latter may be a matter of maintenance only, or it may depend also upon the cost of construction or reconstruction. Maintenance is usually, or should be, the dominating factor. Under the item 'carriageway' in the provision for total width allowance may be made for probable future widening, having regard to the relative economy of widening alternative routes or making new roads. Such a provision for future widening should always be fully considered in laying out a new road in a flat or gently rolling country. In hilly country, and especially on sidelong slopes, it is usually better to allow no such provision between fences, since the future can best be cared for by acquiring land only, the cost of obtaining a given width of flat strip by two earthworks being usually very much less than that of obtaining the same width by one earthwork. For the one wide strip the quantity of earthwork is much greater and the rate for cutting may be higher, while the retaining wall will cost much more than the two smaller ones. With flat earth slopes the total width required may be as great or greater.

Width in Relation to Maintenance.

Width in Relation to Maintenance.—The best width, having regard to the nature and amount of the traffic, will depend upon the materials available and their cost. One width will give a minimum maintenance cost with a hard and costly stone, a greater width may be the most economical for a softer stone. First decide the economical width for each material, and then compare costs. When the traffic is moderate the 'weathering' factor may be important and on little-used roads it may predominate. Usually the economic width for sandstone and flint crusts is greater than that for limestone crusts, partly because the more porous crusts made with sandstone and flint may have flatter cambers, tending to a good distribution of the traffic, and partly because the quartzy materials wear into large grains which are only removed by the heavier rains, while limestone crusts wear into fine stuff which is readily removed. The exposure of a wide surface is, therefore, usually undesirable with limestone crusts. Similar comparisons are furnished by harder stones, such as quartzites, compared with granites which contain much felspar. The nature of the subsoil affects the width, especially if the cost of construction or reconstruction has to be considered, because with soft subsoils, not tolerant of high pressures under heavy wheel roads, it may be better to reduce the pressure by making a deep crust than to reduce rutting of surface wear by making a wide crust. In choosing a material for a given width, imposed by circumstances, the same considerations apply, looked at the other way about.

Width and Traffic.

Width and Traffic.—The width may be decided, partly or wholly, from the traffic point of view. In making a mountain road, or widening a narrow lane, the ruling width may be that necessary for the passage of two loaded vehicles, and, as a matter of safety, a road with walls may be made somewhat wider than a similar road with hedges. In such cases it is important that the edges of the crust should not be steeply cambered or weak, since such conditions reduce the effective passing clearance. On roads of this kind the carriageway is that imposed by the total width, but it is often good economy to carry the actual crust right across, with such change in the nature of the materials near the edges as may be suggested by the relative importance of the margin as a support to the crust or as a surface drain. Apart from such cases, and taking that of the normal carriageway on a road with suitable margins, the widths suitable are, for a very large mileage of country roads generally, either that required for one vehicle at a time, but sufficient for the cautious passing of two vehicles, or that required for the frequent and convenient passing of two vehicles. In both cases, it is desirable to give ample support to the edges, either by under-trenching, with a filling of large-gauge stone, or by continuing the crust under the turf beyond the incidence of wheel loads. Using the word as applying to the measurement from surface margin to surface margin, the following widths are regarded as suitable. For single-line traffic, 12 ft. is a width largely adopted in many countries. Ten feet or even 8 ft. may be sufficient for roads with very little traffic if the soil is suitable and the margins readily accessible. A gravel soil, especially if these strips be sifted a little when the road is made, offers this advantage, as does, under some conditions, a sandy soil. On clay soils, the width of the crust itself should be such as to admit of the passing of vehicles, or the edges of the crust may be broken down by rutting of the clay just beyond. Clay is not easily brought back to its proper level. On account of its hardness in dry weather, however, it makes good margins for narrow 'fair weather' roads, which may be made with a very narrow metalled or gravelled width. For roads on which the passing of two vehicles must be readily accomplished, a width of 16 ft. is very usual, and 15 ft. is enough in countries in which the ordinary vehicles are narrow. In France a considerable mileage of important roads has a carriageway of about 16½ ft., but this may, in some cases, be the economical maintenance width. The usual width of the carriageways of the French Routes Nationales is from 5 to 7 metres, or say, 15½ to 23 ft. An important system of English county roads has an average width of 17½ ft. On very steep gradients it is often desirable to have very wide carriageways.

Camber.

Camber.—The amount of camber may be stated as the total rise in the width of carriageway or as the average slope of the sides. A rise of one-fiftieth is often recommended, or slopes of 1 in 25. Slopes of 1 in 32 have been recommended as an average. Actually, the amount of camber depends upon the nature of the crust, the gradient, the nature of the traffic, the widths and the climate, and no general rules can be laid down. It may be noted, however, that a rise of more than 1 in 50 should not be given without careful consideration to roads with much motor traffic, while there are some roads, especially those with quartzy crusts on steepish gradients, which require hardly any camber. The barrelled camber has the advantage that the suppore which the earth margins give to the edge of the crust is less nearly horizontal than in the cast of a sloped camber (two slopes joined by a small arc in the middle of the road), and the barrel form resists somewhat better a tendency to the formation of ruts on each side of the middle line. The former advantage disappears, however, if the edges of the road crust are suitably designed, and the barrelled camber has the serious disadvantage that the slope becomes steeper near the edges where cyclists ride when they are being passed by motor cars. On roads with much motor traffic the mud is soon shifted to near the edges, this part being often somewhat slippery. An elliptic camber has sometimes the disadvantage that it is too flat in the middle, especially on roads with much motor traffic and of such width that a strip of about 5 ft. width in the middle gets the main part of the wear of the off-side wheels of cars going both ways. The camber with two slopes seems suitable for a greater range of roads than the barrelled form, and the advantage of a tilt to one side only must not be overlooked in the special cases to which such a device applies.

Drainage.

Specific works may come under one or more of the four heads: (1) interception of surface waters which would flow across the road, or along it, or would flood it; (2) interception of seepage water; (3) surface drainage of rain-water from the road and its margins: (4) under drainage of the road bed and crust. In a soil neither very stiff nor very porous, a side ditch may perform all four duties. When on the uphill side of a road it acts as a catch-water drain. It also acts as a channel to carry to suitable outlets the rain-water gathered by the road. It may also intercept seepage water from the hillside or the land above a sunken road; and, if near enough to the edges of the crust, and deep enough, it provides for the establishment of an hydraulic gradient from the crust and the road bed to the ditch bottom or water-level. On a stiff soil it does not perform this function, except to a very limited extent and when deep and close to the crust. In a stiff soil, therefore, a deep ditch is not needed for this purpose, the water being dealt with by surface flow, aided by the filling of all hollows, and by evaporation. A deep ditch may, however, play the part of an interceptor of seepage water, forced through a fairly stiff soil from wet places on the hillside above. Apart from such a purpose a ditch on a stiff soil may be shallow if the necessary capacity can be given by the width available. The stiffer the soil the deeper the drain, up to a point at which it will no longer drain the road bed and may be quite shallow. It is then very important to fill hollows on all parts of the roadside which are above the level of the underside of the crust.

Catchwater Drains.—It is often desirable to have a catchwater drain clear of the uphill fence so that the bank may not be torn by water running down it. The outlets may be clear of the road, or lead to the larger cross culverts. Such a drain and, when necessary, side chains, may be provided with 'drops' or falls of hard materials, to reduce velocity and scour. Catchwater drains are much needed on many English roads.

Side Drains.—For a given soil there is a slope at which water hardly moves through it. To provide for flow, a slightly *steeper* slope, carried from the bottom of the side ditch or shoulder drain, should reach the edge of a waterproof crust, or the middle of a porous crust. This determines the depth of the ditch, or the depth at which the pipe drain in the shoulder trench lies; or it decides which of them will be the cheaper to make and maintain. On porous soils the natural slope of the land may provide drainage; but even then care must be taken that when the road runs directly down the slope there is some easier way for the water to flow than down the road bed and out through the crust; and sudden changes in the soil must be noted and provided for. On a long slope of this kind, on a porous soil, some diversion of subsoil water by trenches filled with clay may be useful, where the water can be turned to a depression in the ground outside the road. Pipe cross drains may be used for the same purpose and if backed by clay on the downhill side will be very effective.

Another function of the side ditch is to prevent seepage water from entering the road bed from surrounding land: and such a ditch may be necessary in addition to a surface catchwater drain on the hillside above it. On a hillside road the drainage from the road bed may be amply provided for on the downhill side, and the side ditch on the uphill side may then be puddled on both sides and bottom, or only on the side towards the road, according as it does or does not deal with seepage water in addition to surface water. As a seepage water interceptor a pipe drain covered in may be quite effective; but in filling in the trench, if the soil is used, any muddy stuff should be put on the side towards the road, and the raw earth on the uphill side

Drainage of the Crust.—This comes under one or two of the main divisions of drainage; surface drainage being the more important on stiff soils, and under-drainage on porous soils, while it may be necessary to make the most of both on soils such as those marls and silts which are at once receptive and retentive of water. If the crust is more porous than the road bed and subsoil it will probably be desirable to provide a drainage course, or bottoming, such as a telford pavement. If the soil is more pervious than the crust such a provision is not likely to be necessary for drainage. When the crust or its bottom course allows of drainage to the sides, but not very rapid drainage, this may be aided by giving a camber to the road bed, which may also be desirable so as to provide sufficient thickness of crust where it is most wanted, towards the edges. Cross-drains are seldom economical. If they are farther apart than the width of the road they are less effective than shoulder drains: if they are nearer together than the width of the road, they cost more than one shoulder drain, or, as they have to be placed deeper, as much as both shoulder drains. Cross drains require many more outlets than shoulder drains. Camber is given to a road so that water may drain from the surface of the crust. Too steep a camber may defeat its object by driving traffic to the middle, so that ruts are formed. When a road is puddled by much traffic in drizzly weather, camber is ineffective as the little ridges of mud hold up the water. On a slope of 1 in 24 a $\frac{1}{2}$-in. ridge of mud holds up a foot-wide puddle; on places worn flat very much wider puddles. Under such conditions the best drain, on an impervious road, is a broom. When the crust is porous and self-draining a very small camber is sufficient, but the outlets to the side ditches must be sufficiently numerous and effective, or the road will be flooded during rain. On a road with no gradient it may be necessary to have flush edges, that is, no raised water-tables; but with a very small gradient this is unnecessary as the water will flow to the outlets. To prevent scour and the cutting back of their beds till the crust and road bed are attacked, the outlets through turf margins must not carry the water with too high a velocity. The formation of a delta with the road washings may be allowed, the stuff being cleared away when the level of the delta becomes too high and the outlet is ineffective. Generally, a porous road crust need not have a steep camber if any of the following conditions are fulfilled: (1) good drainage of the crust, with shoulder drains if necessary; (2) a porous subsoil with a low, normal subsoil water level; (3) a porous subsoil on an embankment, or drained by effective side ditches. An *impervious* crust need not have a steep camber—(1) on gradients, especially if fairly steep; (2) if kept clean; (3) in dry and in showery climates or where the rains are usually heavy, as opposed to damp and drizzly climates.

Drought.

Owing to the presence of clayey matter as a constituent of many important road stones the weakness of road crusts when too wet has received more attention than their weakness when too dry. Sandy materials, on the other hand, resist wheel loads and disturbance generally better when damp than when dry. Drought, therefore, injures such roads, including crusts made with quartzite, sandstones, and flints (apart from dust as a nuisance). Other roads may be seriously affected by droughts which cause a crumbling of the margins, or the gaping of a clay soil, the effects being observed when heavy rains occur. Drought may be combated by shade, either of trees or hedges, and by care in carrying out drainage so that the soil is not made too dry. Dead leaves are beneficial on sandstone and flint roads, and various materials, more or less imitative of the gummy decay of the leaf, have been used to lay dust, or to bind road crusts of a sandy character.

Road Crusts and Wearing Layers.

By Francis Wood, M.Inst.C.E., F.G.S., author of 'Modern Road Construction.')

The macadam roadway is the prevailing structure throughout this and other countries; it is a cheap and easily attainable form of construction, but whenever it has been subjected to heavy traffic it has failed and has had to be substituted by asphalt, wood, or sett paving.

A wood paved road under a certain amount of heavy traffic will wear probably $\frac{1}{4}$ in. per annum, whereas a macadam road would wear in the same period under the same traffic about 2 ins.; a granite sett pavement would wear to a lesser degree than the wood pavement.

The wear of a macadam roadway is due 10 per cent. to the traffic, 5 per cent. to the weather, and 85 per cent. to internal attrition. The stones in a macadam road are not bound together, they are merely consolidated, and the material which fills the interstices only aids in retaining the stones in their positions, but these become so loose that the traffic coming upon them causes them to grind on each other, so that they diminish in size until the structure largely becomes small material, the weather conditions then developing this fine material into a slimy mud.

The wear due to tractional resistance is extremely small, the wear to internal attrition extremely large, the presence of moisture aiding the latter process. This being the case, if the stones can be bound together by a good binding agent, so that this movement and grinding action is prevented, this form of wear will disappear and the cost of maintenance will materially decrease.

Tar spraying has in some slight degree assisted in this object, but 'tar macadam' is much more satisfactory.

Bituminous compounds of bitumen, sand, cement, etc., are still more effective, and the asphalt macadam which has been laid in Fulham and other places has had success up to a limit.

Investigation has demonstrated that large stones should not be included in the surface of a structure which is to be submitted to heavy traffic and which includes bitumen as a binding agent. The material is not at fault, but the large size of the stones causes the failure.

No constituent particle should be of greater size than ¼ in. diameter in the wearing surface, which in the ordinary road need not be more than 1 in. thick. But such a wearing surface has no inherent stability and would not have a satisfactory result unless provided with a substantial base. This can be provided by a bituminous concrete, which may be formed of the usual macadam sized stones and such fine material as would be found in the macadam portion of the structure of a road; this may be mixed with a pitch softened by tar oils to a state that is flexible when cold, or a composition of pitch, bitumen, etc., may be used. This base need be only 2½ ins. to 3 ins. thick, and if it is placed on a substructure which is reasonably solid in all conditions of the weather and free from moisture, such a road will successfully withstand traffic of a heavy character for very many years and at a low cost of maintenance.

Roads on these lines have been built in Fulham and in the country (Surrey, etc.,) at a cost of between 4*s.* 6*d.* and 5*s.* per sup. yard (pre-war prices).

APPROXIMATE GRADING ANALYSIS.

Base.		Wearing Surface.	
45 per cent.,	1½ in. stone	200 mesh,	18 per cent.
25 ,,	½ in. chippings	100 ,,	17 ,,
25 ,,	sand	80 ,,	17 ,,
5 ,,	200 mesh	50 ,,	35 ,,
		30 ,,	6 ,,
		20 ,,	4 ,,
		10 ,,	3 ,,
100 ,,			100 ,,

By weight the amount of bitumen would be 9 per cent. and 14 per cent. respectively.

The cost of wood paving in Fulham may be gathered from the fact that the Council allotted 10 years ago the sum of 4,000*l.* per annum to maintain 160,000 sq. yards; this has now been increased to 202,268 sq. yards without increase in allotted sum. Any surplus not spent is placed to a reserve; this reserve at the end of 1916 was 12,000*l.*, sufficient to repave one-seventh of the whole area. The average cost is therefore 5*d.* per sup. yard per annum; the cost of the heaviest trafficked road does not exceed 9*d.* per sup. yard, even allowing for the concrete foundation. It has been stated in the Committee Rooms of the Houses of Parliament that local authorities have roads which cost over 2*s.* and which are of macadam.

The motor bus damages the road to no greater extent than the steam lorry, if as much, as many of these have steel tyres.

(*Francis Wood.*)

The Strength Crust and the Wearing Layer.

The word 'foundation' is often misapplied. It should properly be used for the special bottoming that is necessary on soft soils, and sometimes on clayey soils, in order that a distinction may be made between such preparatory work and the construction of the actual 'crust,' which plays the principal part, or is the sole agent, in distributing the load. The essential nature of the crust is the same, whether it distributes the wheel loads upon the natural soil or upon a bottoming of hard material, and whether it receives the wheel loads in their full intensity or partly distributed by a carpet of considerable strength and thickness. Thus, the so-called 'concrete foundation' of a wood-paved road is really the strength crust, and the wood-paving is the carpet or wearing layer, and on a bad natural soil the concrete crust will need something in the nature of a foundation proper.

These considerations are of special importance at the present time, because recent developments point to the value of an ordinary waterbound broken stone crust, as what is called 'a foundation' for a carpet of bituminous materials, or stone setts, wood blocks, or bricks; and it must be remembered that the extent to which the loads are spread by any of these carpeting materials is so small that the old crust should be brought up to its full strength, as a strength crust sufficient for the traffic. Further, in using materials with bituminous binders, it is possible to effect so good a bond with water-bound materials in the lower course that the whole thickness acts as one crust, the square of the depth of this crust being the measure of its beam or slab strength as well as of its effect in spreading the load as a cone. It is, therefore, very necessary that such a condition should not be confused with the condition when the wearing layer of relatively costly materials is quite thin, only thick enough to serve as a wearing carpet. There is a strong tendency towards the adoption of this plan, because the cost of making one set of materials quite effective in wear-resistance and another set effective in strength and resiliency tends to be less than that of using materials which have both qualities.

Comparisons of Pavings and Carpets.

When, therefore, we weigh the evidence in favour of stone setts, wood blocks, bricks, bituminous carpets and so forth, it must be remembered that these materials form the wearing layers and, in some cases, shock-absorbing layers, and that the value and economy of each class of paving or carpet depends largely upon the nature and cost of the strength crusts on which it can successfully be laid.

The Waterproof Carpet.

In view of the importance of possible developments in the practice of laying wearing carpets on water-bound, broken-stone road crusts, it is necessary to consider whether such a crust continues to maintain its strength when it is no longer water-bound. If a road-bed is so situated that no water will reach it from beyond the edges of the crust, and if a layer is spread over it, effective in preventing the access of water to it but not preventing the gradual escape of all moisture, the crust will become dry and be no longer water-bound. Tarred roads which are thus rendered very dry sometimes compare unfavourably as regards corrugations with other roads which have been less effectively waterproofed, or which are kept moist by the creep of water in the road bed. In places where this too dry condition of a water-bound crust is a serious matter, a slightly porous brick, or a paving with slightly porous joints, is worth consideration, or the replacement of the whole crust with bituminous-bound materials.

Water-bound Broken-stone Crusts.

In the ordinary water-bound, broken-stone road crust the wearing layer is simply the top part of the strength crust. Usually, the stone in this top portion is harder or tougher than that in the rest of the crust and differently graded, and it is therefore necessary to take care that the change in materials as the crust is built up from the first course of stone is not accompanied, at any stage, by the formation of a plane of division. There must be no hard surface and no parting layer within the crust when it is finished.

Binding Material.

One of the most frequent causes of the too rapid wear of both new crusts and repairs, especially repairs, is lack of sufficient binder. The use of too much earthy binder instead of a gritty binder, such as stone dust, is also a cause of too rapid wear. The former weakness, lack of binder, is, however, a much more serious and widespread weakness than is usually supposed, especially on secondary roads in some areas and by-roads and lanes in other areas. If no suitable binder is available when holes are filled with loose stones, it is better to use mud than to use nothing at all, and mud is better than dry earth, because the water comes to the top.

Segregation.

It is very necessary to avoid segregation. A mixture of stone and binder, supplied in the proper proportions, is ineffective, and fails to form a tough and durable crust if there are patches in which one size or another is in excess of its proper proportion. This applies also to the finishing of a road surface by filling considerable hollows with chips before the final rolling. The crust when finished should be practically mass concrete with its own true surface. The final touches should be of the nature of grouting, not rendering.

The Telford Road Crust.

In the case of a crust of the telford type, in which large stones are placed with their lengths transversely to the road, the spaces packed with chips or gravel, and a layer of broken stone and binder formed over this, it is necessary either to treat the lower course as a foundation and to make the upper course adequate as the strength crust, or, which is usually better, so to form the upper course that its stones penetrate the gravel or chips of the lower course, and the whole thickness forms one strength crust. On very bad, wet ground the former plan is the better, that is, to treat the lower course as a foundation only, and make it not too compact for effective drainage.

Single Crust Roads.

In addition to the preceding notes, it may be pointed out that if the single crust is to have a fair chance of success, the road bed should be very carefully prepared. It should be brought to the correct shape, usually cambered, and it should be made of the same degree of hardness throughout, by ramming, and adding earth and ramming again, and, where necessary, by loosening before ramming. When a bottoming of gravel, or large stones, or a mixture of both, is used there should still be some preparation of the natural soil if it is of varying degrees of density; and it should always be brought to about the right camber. Otherwise, material is wasted, and the degree of resistance in the foundation varies, tending to the development of humps and hollows in the crust. Hollows in the road-bed should not be filled with the foundation material, but with material as similar as possible to that in the road-bed itself. Road crusts should *not* be thinner near the edges than they are in the middle part.

TAR-MACADAM.

There are in ordinary use two ways of forming a bituminous-bound road crust. If the stone is coated beforehand with the tar, and allowed to stand until the coating is tacky, the crust can be 'consolidated' with a moderate amount of rolling. The extent of consolidation will partly depend upon the extent to which the stone is graded. As a rule, very little grading is regarded as necessary, the surface being closed by rolling in ¾-in. to ½-in. material. The other kind of crust, formed by 'pitch grouting,' usually consists of stone graded through a wider range, the smallest material being sand, added with the pitch, which is poured in hot. The surface is closed with small material. For tar macadam the 'general directions' issued by the Road Board recommend at least 60 per cent. of 2½-in. stone and not more than 30 per cent. of 2½ to 1¼ in., the remaining 10 per cent. not being in the body of the crust but being used for closing (¼ to ½-in. stuff). For pitch-grouting, the sizes are: 60 per cent. of 2½ ins. and 35 per cent. of sizes *graded* from 2½ ins. to 1¼ in. In addition 5 per cent. of chips are to be used for closing after the pitch has been grouted in. The body of the crust will, however, contain a proportion of sand, equal, by measure, to that of the pitch. The quantity of pitch varies according to circumstances, but ordinary quantities, noted in the 'general directions,' are 1¼ gall. per sq. yd. for a 2-in. layer, 1⅛ gall. for a 2½-in. layer, and 2 galls. for a 3-in. layer.

The pitch used (Road Board specification) is to be thinned with tar oil in the proportion of 10 to 12 per cent. (of the whole). The pitch itself should not have more than 22 per cent. and must not have more than 24 per cent. of free carbon. The tar oil must have a specific gravity between 1·065 and 1·075 at 20° C. and must be commercially free from light oils and water.

Tar-macadam road crusts have been successfully made with stone of considerably smaller average sizes than the above.

Cost of Plant.—Very simple apparatus is used in many cases for drying the stone before tarring it, and for coating it with the tar. In other cases, specially devised plant is used. A plant at Stourbridge, including a 2-ft. revolving cylinder, 10 ft. long, inside a 3-ft. shell, and driven by a 5½ h.p. gas-engine, cost 350*l.*, and with it some 40 to 50 tons can be heated and mixed by three men in one day. The proportions of cost shown by a recently erected plant at Belfast are: broken stone and screenings, 60·67 per cent.; tar, etc., 11·49 per cent.; wages and cartage, 21·25 per cent.; tools, oil, etc., 1·94 per cent.; repairs and fittings, 4·65 per cent.

Limiting Gradient.—The limiting gradient for tar-macadam depends a good deal upon the materials employed, and upon the special means taken to provide good foothold. For ordinary tar-macadam about 1 in 25 is regarded as the limiting gradient, but 1 in 30 or even 1 in 35 is sometimes preferred. In considering the possible use of tar-macadam in country districts where it is unknown, regard must be had, as in the case of any hard paving, to the nature of the road surfaces to which the horses of the district are accustomed. London horses, for instance, have learned to skate, and to walk on the tips of their toes.

Material.—There is no doubt that, on the whole, materials which are slightly porous and have roughish surfaces give better results than denser and smoother materials. It is impossible to say to what extent this is due to porosity, or how much of the effect is due to roughness. Certain limestones and tough slags of the right quality have given good results for many years. The results of recent work with Kentish ragstone and other siliceous stones should be watched.

SURFACE TARRING.

Surface tarring has been found to be the best means hitherto tried of abating the dust nuisance, and it considerably reduces the noise of traffic. To get the best results tarred roads should be swept, and the dust removed, at intervals of a few days in dry, calm weather. The dust from tarred roads is, in several respects, worse than ordinary dust.

General Policy.—At the present time the best results seem to follow the practice of tarring once only, except where the tarred surface is completely worn off before the autumn, and allowing the tar and some of the stony material of the crust to wear down by the winter. This prevents the road from becoming jolty and provides good foot and wheel-hold for the winter. Tar which remains below the surface is not harmful, but excess of tar, producing a greasy emulsion on a hard road, or thick, greasy mud in damp places, is to be avoided.

Conditions affecting Results.—Wind and free play for local air currents are needed to keep tarred roads cool. Roads exposed to wind and air currents will suffer little from sunshine; roads in airless places suffer much from sunshine. Roads in cuttings, and those flanked by walls and close palings, and especially if they run across the direction of prevailing winds, suffer from high temperatures in summer and from greasiness due to damp conditions in winter. Shade in itself is beneficial, both as regards the effects of sunshine and with respect to the frequency of frosts. Porous road crusts absorb more of the tar than impervious crusts, which reduces difficulties arising from high temperature or from greasy conditions. A dry and showery climate is much more favourable than a damp and drizzly climate, as regards both the work of tarring and the results obtained. Tarring is more useful in parts of England where it is difficult to make drought-resisting roads than in those parts where such roads are made with success.

Cost of Tarring.—An ordinary cost is 1*d.* to 1½*d.* a square yard, a good deal of work being done at about the lower figure or a little over. In the year 1910–1911 the Buckinghamshire roads, 117 miles, cost ¾*d.* per square yard. Main roads often cost about 50*l.* a mile per annum for tarring alone. No substantial saving in total expenses has yet been shown to follow the practice of surface tarring, except as regards town scavenging (see 'Town Paving'). One gallon of tar is usually sufficient for spraying 5½ square yards of road surface, and a gang of six men with a 320-gallon boiler will tar-paint 5,000 square yards in an ordinary day's work. For recent figures see 'Costs data' at the end of this section.

Nature of the Tar.—Tar of the right consistency can be got by adding pitch to crude tar. It is better, however, to get the proper consistency by heating the tar until the lighter constituents are driven off, since their presence is in itself a source of trouble. The Road Board specifications describe two tars, No. 1 and No. 2, the latter, which is the denser, for use only on warm, dry roads, and suitable for painting worn places. Tar No. 1 has a specific gravity of 1·16 to 1·22 at 15° C. (1·19 recommended). It must have not more than 1 per cent. of water and ammoniacal liquor. The free carbon should not exceed 16 per cent. by weight. Tar No. 2 has a specific gravity of 1·18 to 1·24 at 15° C. (1·21 recommended), and must be free from water. The free carbon should not exceed 18 per cent. by weight.

Method of Application.—The road should be dry and warm. The surface should be brushed hard to remove all dust and loose particles, the second brushing being in some cases done with soft brooms. The tar in the boiler should be at about boiling point, say 220° to 240° C. Its temperature when delivered on to the road will depend on the mode of application. Various machines are employed, with the object of getting good penetration, delivering hot tar under pressure; but the amount of penetration depends much more upon the nature and condition of the crust. Machines resembling water-carts do best on smooth roads which are true to shape. The spray, a fine rose at the end of a flexible tube, is used by hand, with the advantage that the quantity of tar applied to different parts may be varied if necessary. The spray is very effective in coating the stones with a clinging film, after which the required thickness can be sprayed on as desired. It works well on uneven roads. Tar can be successfully applied by hand, poured on and brushed in. The Road Board recommends three-gallon cans with spouts not less than 1½-in. diameter.

Blinding the Surface.—When the freshly tarred surface can be left for some hours undisturbed, this is usually done. On porous roads, or where the quantity used is small, it may be sufficient to blind this somewhat hardened surface with dust only: clean dust from the preparatory sweeping or destructor dust. In other cases, varying quantities of sand are added, or stone chips, the quantities and method of application depending upon the extent to which these materials are intended to form a mat with the tar, or to act as a temporary protection. Chips may crush to a kind of filling coat, or they may be used so as to form a definite mat. Sand may be added so as to form a mat, or may be strewn a little at a time so as to avoid the forming of a too sandy and brittle mat, but at the same time to act as a parting layer between the tar film and the wheels of vehicles. Some of the sand, if not removed by rain, may be swept off when the tar has hardened and the road is becoming dusty.

Recent Practice : Crusts and Carpets.

The following descriptions of recent practice relate in some cases to the whole road covering and in other cases to carpeting only. In some cases only a few details are given, or references to places and dates. In other cases the methods are described at some length, or are abbreviated from descriptions by the engineers responsible for the work. The views taken of the merits of particular materials or methods are not necessarily shared by the Editor, nor by the writer of the section.

At the present time neither plain nor reinforced concrete is in use in the British Isles, except in a few places, the total mileage being quite small and almost or entirely in towns. The value of plain concrete for streets with only a small traffic has been proved by experience in several places, and attention is properly being directed to the advantages of reinforced concrete as a strength crust, which is a matter quite independent of its efficiency in providing also the wearing surface. It may be remarked that, with reference to the use of concrete roads in the United States, Professor Blanchard and the members of the Highways Construction Board, New York, are to a large extent opposed to the construction of concrete roads. The case for reinforced concrete roads is forcibly put by Mr. J. F. Butler (p. 731).

A material which is almost unknown as a paving for roads or streets in this country is brick It has its advocates, however, and therefore finds a place in the following pages, the nature of the brick to be used and the method of laying the pavement being fully described by Mr. Alfred B. Searle (p. 732). Brick roads have been used in the United States for many years, and the trend of opinion in that country during the next year or two will probably have considerable weight with British road makers.

Bituminous Macadam Roads.

(Abbreviated from a description by A. W. Dean, Chief Engineer, Massachusetts Highway Commission.)

A gravel, or suitable sand, foundation may not be needed. If a stone foundation is made on a clay subsoil, the interstices should be filled with gravel to prevent the clay working up.

First course.—The thickness of the first course, of broken stone, depends on local conditions. For instance, if a 10-in. foundation is necessary, the first course of the crust need only be about 2 ins. thick. If no foundation is necessary, the first course of the crust should be not less than 4 ins. after rolling, or 6 ins. for heavy loads. The stones of this course may vary from $\frac{1}{2}$ in. to 3 ins. in longest dimensions, but the percentage of the small size should be very small. For a course of 4 ins. or less a good size is $1\frac{1}{2}$ ins. to $2\frac{1}{2}$ ins. In a 6-in. course the maximum size may be 3 ins.

The voids must be well filled with fine material to prevent loss of bitumen from the upper course. The surface must be even. All surplus dust and fine material must be swept off, leaving the upper stones bare to receive the second, or bituminous, course.

Bituminous course.—The second, or bituminous, course to be 2 ins. thick, or 3 ins. for heavy vehicles in large volume. The stone must be of good quality and uniform in character, and the sizes not segregated. The best results are obtained with stone from $\frac{3}{4}$ in. to $2\frac{1}{2}$ ins., the larger sizes predominating, although the course be only 2 ins. thick. The rolling should be thorough.

Application of bituminous material.—This is applied at a temperature of 250° to 300° F., with a mechanical distributor, with a force equivalent to that obtained under a pressure of 30 lbs. per square inch, or more. The amount per square yard is from $1\frac{1}{2}$ gallons on a 2-in. course to about 2 gallons on a $2\frac{1}{2}$-in. course. It should be very evenly spread.

Surfacing.—The surface should be lightly but completely covered with pea stone ($\frac{1}{2}$-in. stone) and thoroughly rolled with a 15-ton roller, if available, and if the stone is of hard quality, and a lighter roller for a poor quality stone.

Seal coat.—A seal coat of the same quality of bitumen is applied, half a gallon per square yard, covered with pea stone, and finished off with a heavy roller. When the bitumen is applied the stone must not be wet but may be moist. It must be clean and free from dust.

Bituminous Carpetting.

(Abbreviated from a description of work carried out in Kent. County Surveyor of Kent, H. T. Chapman, M.Inst.C.E.)

The work is done in two operations. The base coat of local stone, flint, scarified material, or clinker, mixed with bituminous material, is laid hot to form a nearly voidless concrete, not less than 3 ins. thick. For the carpet, sand, grit, or selected crushed clinker is graded between a 200 and a $\frac{1}{4}$-in. mesh and mixed with from 13 to 15 per cent. of bituminous material, and laid at a temperature of 300° to 350° F.

In a specific case, 1914, the base coat was 3 to 4 ins. thick, of crushed shingle and flint, $1\frac{1}{2}$-in. to $\frac{1}{2}$-in. gauge, coated with a pitch and tar mixture, 8 parts soft pitch to 3 parts tar. The carpet was $1\frac{1}{2}$ ins. thick, of grit 31 per cent., sand 56 per cent., and bitumen 13 per cent. All these ingredients were heated to 350° F. and mixed. The carpet was first cross-rolled and then consolidated with a 10-ton roller.

Costs.—Costs were, base coat, 2*s.* 6*d.*, carpet, 2*s.* 7*d.* total, 5*s.* 1*d.* per square yard, the prices of the materials being at practically pre-war rates.

The results have been very satisfactory.

According to the remarks of several speakers at a meeting of the Institution of Municipal and County Engineers, asphalt macadam, as a wearing surface for roads, should be laid in one coat. It can apparently be laid in one thickness of $3\frac{1}{2}$ ins. quite satisfactorily, whereas if put down in two layers the upper part creeps or peels off under traffic.

Slipperiness.

Slipperiness, especially in the autumn, is one of the defects of several types of surface-tarred and bituminous-bound roads. There is, as yet, very little agreement amongst road surveyors as to the best preventives. The thorough rolling in of stone chips when the road is tarred may be recommended, and crushed flint has been successfully used. Such measures may be taken in warm weather towards the end of summer. To a certain extent the possibilities of incorporating stony material in a tar film are limited by the necessity for the maintenance of that film, as such; but this does not apply to bituminous-bound roads.

Tarco.

'Bi-Tarco' and 'Tarco B' are specially prepared compounds (supplied by *Fleming & Co. Glasgow*), the former for grouting and the latter for road painting, for which it is exceptionally well suited. The compounds are noticeable for wearing qualities and for cheapness and safety

SPECIFICATION OF WORKS TO BE DONE AND MATERIALS EMPLOYED IN CONSTRUCTING A WOOD-PAVED ROADWAY.*

Sand.

1. The sand is to be pit or Thames sand of the best quality, clean and sharp, and free from loam or clay.

Thames ballast.

2. The Thames ballast is to be clean, the stones are to be regular in size, and the proportion of sand to stones is to be to the satisfaction of the surveyor.

Cement.

3. The cement is to be best Portland cement, complying with the British Standard Specification, of a pale grey colour, specific gravity of not less than 3·15, or 3·10 one month after grinding, and capable of sustaining an average tensile stress of not less than 400 lbs. per sq. in. of sectional breaking area seven days after gauging and immersion in water twenty-four hours after gauging, and 500 lbs. per sq. in. of section twenty-eight days after gauging, and is to be delivered into the works in sacks, weighing 200 lbs. net, marked with the manufacturer's name. It is to be ground so that, when sifted in a sieve of 5,776 meshes to the sq. in., there shall not be a residue of more than 3 per cent. Sufficient cement is to be stored in or near the works for a fortnight's use fourteen days before the commencement of the work, and an equal quantity is to remain stored during the progress of the work until only sufficient work remains to be completed to use up the cement stored during the work. The cement will in all cases be tested by the surveyor with Adie's Testing Machine, and the average taken of at least six tests, and any rejected by him is to be at once removed from the work without any question being raised.

Concrete.

4. The concrete is to consist of one part of Portland cement and six parts of clean Thames ballast (large stone to be in no greater proportion than 60 per cent.), the parts being ascertained by measurement of their volume in proper measures, thoroughly mixed together in a dry state on a timber stage not less than 10 ft. by 10 ft. for half a cube yard of concrete ; water is then to be added from water-can through a rose, and the whole again thoroughly mixed until a proper consistency is obtained. If the concrete has commenced to set before being used, it is not thereafter to be used except as ballast.

Cement grout.

5. The cement grout is to be made of one part of Portland cement, as described, and three parts of clean sand (the parts being ascertained by measurement of their volume in proper measures), thoroughly mixed together in a dry state on a proper banker, and made as previously described for concrete.

Cement mortar.

6. The cement mortar is to be composed of one part of Portland cement, as before described, and three parts of clean, sharp sand mixed on a proper banker, as previously described for the concrete, and used while fresh.

Thames ballast for top dressing.

7. The Thames ballast for top dressing is to be crushed and then screened through a ¾-in. mesh sieve.

Excavation.

8. Excavate the whole of the carriageways as directed, including cressings, channellings, etc., wherever necessary, to the proper depths and levels as required, carefully separate the macadam, set aside for re-use, fill into contractor's carts, and deposit where directed within a radius of one mile from the job.

Strip roads.

9. Carefully strip roads of all old wood blocks and cart away to wharf, depot, or where directed.

Existing channel.

10. The existing granite kerb, or sett channels, paved areas, binding courses, crossings, and concrete under, where described or necessary, is to be taken up and carted at the contractor's expense to the wharf, depot, or as directed. So much of the existing kerb as approved by the surveyor is to be set aside, rejointed, and relaid on Portland cement concrete 8 ins. thick, making out with new 12-in. by 8-in. kerb to be obtained from the Borough Council.

* Extracted, by permission, from 'Modern Road Construction,' by Francis Wood, M.Inst.C.E., F.G.S., Borough Surveyor of Fulham.

Floating.

11. The surface of all existing floating is to be picked perfectly free from all pitch, asphalt, old floating, soft concrete, etc., in such a manner that the new floating will not alter the existing contour or increase the height of existing foundations unless otherwise directed; the same is then to be brushed clean and free from dust, well drenched, and finished with a floated surface, $\frac{3}{4}$ in. in thickness, composed of one part Portland cement to three parts sand, as described for cement grout. The surface of new concrete to be finished in a similar manner with proper and approved contours and with satisfactory falls to gullies. The finished level of this surface to be exactly 5 ins. below and parallel to the intended surface of the wood pavement. All floating after completion to be left exposed for seven days or longer, as considered necessary by the surveyor.

Laying of wood blocks.

12. After the rendering specified above has been laid sufficiently long to become thoroughly hard and set, it is to be brushed clean, the block to be dipped in a hot mixture of pitch and creosote, or anthracene oil, and then to be quickly laid in position, butt-jointed, and in parallel courses across the road.

Wood blocks.

13. The timber from which the blocks are to be cut shall be carefully selected fourth Swedish close-grained, yellow deals, bearing the shipper's mark, and which must be described in the current *Timber Trades Journal List*. The blocks shall be of uniform size and weight and uniformly cut. The timber shall, before being cut, be submitted to the surveyor or his representative, and no blocks shall be sawn from timber of which the surveyor or his representative has not signified his preliminary approval. Four samples sealed and marked with the contractor's name and shipper's marks shall be left at the surveyor's office for his examination with the tender, and any blocks which may be brought on to the works and which may be inferior to these samples may be rejected by him. The surveyor or his representative shall have full power to reject any blocks, either at the cutting yard or at the creosoting works, and he shall also have power to reject any blocks after delivery on to the site of the proposed works, or at all or either of these places, whether creosoted or not, or which are not creosoted in a satisfactory manner, or to the extent of 10 lbs. of creosote to the cubic foot of timber, or with a satisfactory quality of creosote. The blocks when cut shall be truly square and shall measure 9 ins. by 5 ins. by 3 ins. off the saw. The annular rings shall not be less than 10 to the inch, not more than 2 ins. of sapwood shall appear in any block, and the percentage of such in bulk shall not exceed 15. They shall also be free from large, loose or dead knots, shakes or other defects, and shall not contain more than 5 per cent. of waney edges. Timber that has not been properly stored and become dry will not be accepted. Care must be taken to prevent the blocks from becoming wet, as any in such a condition either from rain, bilge water or other causes, must not be creosoted.

Creosoting and creosote.

14. The Council shall appoint a representative to examine the blocks, who shall have power to cause the blocks to be spread on the ground before being creosoted, and to cut or mark as arranged by the surveyor any block he may reject. The blocks after being approved may then be creosoted, a sample lot with each charge being weighed both before and after the process. The creosote to be forced under pressure into them until they have absorbed an amount of 10 lbs. to each cubic foot, and in such a manner that any block split open will show the creosote to have penetrated right through.

15. The creosote is to be a liquid heavy oil of tar, commonly called creosote, and is to contain not less than 8 per cent. of tar acid. It will be subjected to analysis, and the contractor is only to use such as may be approved by the analyst.

Expansion joint.

16. The contractor shall provide wooden battens $1\frac{1}{2}$ in. wide by the depths of the blocks, which shall be used in the channel against the kerb, and the blocks shall be paved up to it. After the paving has been grouted in, these battens shall be withdrawn and the space left shall be filled in with clay and gravel as directed.

Examination of blocks.

17. After the wood blocks are in position they will be examined by the surveyor, and no portion of the paving is to be grouted in with either the asphalt or cement until this examination has been made and sanction given for the grouting to commence.

Composition between joints.

18. Approved pitch or bitumen is to be heated and run between the blocks to a depth of 3 ins. as directed.

Cement grouting.

19. The blocks are then to be grouted with cement grout until the joints are thoroughly filled

Protect for forty-eight hours.

20. After the completion of the grouting the work is to be protected for at least forty-eight hours before the road is thrown open for traffic.

Crossings.

21. At the intersection of other streets the crowns of the adjoining streets are to be adjusted to run into the crown of the roadway that is being paved for that purpose, and whenever it may be necessary, the existing roadways or part or the whole of the crossings to the adjoining streets are to be taken up and relaid with similar materials or with new blocks as directed, making good with new where necessary in the opinion of the surveyor without any extra charge over the amount of the contract. At such intersections the wood blocks are to be laid diagonally as may be directed by the surveyor.

Binding courses.

22. Two courses of 7 ins. by 5 ins. by 3 ins. granite setts laid on 6 ins. concrete are to be laid as a binding course wherever the wood pavement would otherwise abut against a macadam road. The contractor may retain, re-dress, and re-use sufficient of the old setts on the works for this purpose as approved by the surveyor.

Two coatings of siftings.

23. After the road has been inspected a coating of $\frac{3}{8}$-in. crushed ballast for top dressing as specified is to be spread over the wood pavement, and the pavement is to remain fenced in as described, before the road is thrown open to the traffic. An additional coating is afterwards to be spread over when directed.

Facilities to be afforded for traffic and passengers.

24. The work shall be done at such times and in such portions as the surveyor shall direct, and the workmen shall at all times afford such facilities for local traffic or the convenience of shopkeepers as may be directed by the surveyor.

Wood to be laid to proper falls.

25. The contractor must lay the blocks to such levels as are sufficient to satisfactorily convey away all water that may collect on the surface and in the channels at any time, and the work will not be taken over by the Council until this is done to the surveyor's satisfaction.

Contingencies.

26. Provide the sum of £ for contingencies. This sum to be deducted in whole or part from the contract as may be directed. The contractor must fill in the annexed schedule so far as the items refer to any portion of this contract.

Incidental works.

27. The contractor's price per superficial yard for supplying and laying wood blocks 9 ins. by 5ins. by 3 ins. off the saw is to include for all necessary cuttings, raising manhole tops, ventilators or other covers, stop-cock boxes, gully tops, making good to existing wood paving, relay crossings, binding courses, and all works incidental thereto and necessary in order to leave a perfect and satisfactory job.

CONCRETE ROADS, INCLUDING WEARING SURFACE.

Leith.—Burgh Surveyor, J. R. Findlay.

Concrete roads have been used in Leith for more than thirty years, for side roads with little traffic. Concrete has not been found satisfactory under heavy traffic and has had to be replaced by other materials. The concrete crusts are 6 ins. thick, without reinforcement, the finish being 2 ins. of granite and cement, 2 to 1.

Some Examples.—The following examples of the use of concrete are from an article by R. L. Bendall, *The Surveyor*, August 29, 1919 :—

Inverness.—Approach road to goods station, laid in 1865.

Edinburgh.—Gillespie Crescent, laid thirty-four years ago, 10 ins. thick, mass concrete.

Exeter.—Gandy Street, a narrow street, concrete, with stone channels, thirty years old, in good condition.

Dundee.—Streets near the cattle market, thirty years old. Traffic not heavy; condition good to-day.

Melbourne.—Reinforced concrete laid about 1914. Cost of maintenance, ½*d.* per square yard per annum. Carries ordinary town traffic, including motor omnibuses.

Long Island, New York, 1917.—Reinforced concrete road 5 ins. to 7 ins. thick across boggy ground.

Dunfermline.—Reinforced concrete road on clay foundation. One-third of a mile long The only expense in maintenance is tar-spraying. Carries ordinary town traffic, motor omnibuses, and naval base traffic.

Chester.—Many successful concrete roads. The City Council has decided to spend 30,000*l.* on reinforced concrete roads.

Costs.—Costs in 1919 were from 10*s.* to 16*s.* per square yard.

Further Examples and Data.

Dundee.—A piece of road 142 ft. in length has been constructed of unsurfaced reinforced concrete, 27 ft. wide. The crust is 6 ins. thick, the concrete being 1 to 4½; the aggregate of equal portions of 1½-in. and ¾-in. whinstone. The expansion joints are made of sheet steel and two ½-in. layers of bitumen. There is ⅛ in. of bitumen at each kerb. Various kinds of reinforcement were used, ½-in. rods being found preferable to mesh reinforcement.

Canada.—Toronto-Hamilton road. This stretch of road is 35½ miles long. It was opened in 1917. It is of one-course concrete; 1 : 1½ : 3. The thickness is 8½ ins. in the centre to 6 ins. at the edges.

Michigan (Wayne).—Two-course concrete roads were made, the bottom course 4 ins. thick, in 1 : 2 : 5 (limestone), the upper course 2½ ins. thick, in 1 : 2 : 3 'cobblestone.' This method has been *superseded* by a one-course crust, 6½ to 8 ins. thick, of 1 : 2½ : 3 concrete (granite and pebbles). The expansion joints are made with two soft steel plates, 3 ins. by ½ in., and two thicknesses of 3-ply asphaltic felt, ½-in. thick, the full depth of the concrete.

Tilbury.—Dock Road. An experimental section of reinforced concrete road was opened in Dock Road, Tilbury, at the end of 1917. This piece of road is 130 ft. long by 27 ft. wide and the crust of reinforced concrete is 7 ins. thick, the reinforcement, in the form of 'fabric,' being 1½ ins. from the surface. The cost was just under 10*s.* 3*d.* per square yard. It is reported that after more than a year's service this road has proved very satisfactory, free from mud or dust, and costing nothing for repair or maintenance.

London-Dover Road.—Experimental stretches on the London-Dover main road were reported as not proving very successful, partly owing to the concentration of traffic on one-half width after twenty-eight days for setting. It was found that results were improved when a 6 to 1 mixture for the whole thickness was modified to a 6 to 1 mixture for the lower 4½ ins. and a 3 to 1 mixture for the top 1½ ins.

Some Difficulties.

As regards country roads of ordinary width serious difficulties in the use of a concrete crust which is also the wearing layer, are: the necessity for allowing time to set; the practical difficulty in keeping one-half of the road closed for a month or more; and the resulting joint of hard to fresh concrete.

Alternatively, there is the difficulty, both in law and fact, of completely closing a road in long stretches for a period of a month *plus* the time it takes to get through with the concreting of the stretch of road in question. There is also the question whether concrete is suitable for the surface of a road to carry the mixed traffic of to-day, including fast-travelling heavy lorries.

Generally.—The weakness of joints, as regards strength and wear, is one of the chief difficulties in the adoption of the concrete wearing crust. It has been found that joints become 'frayed,' and open up. As in the case of strength crusts of concrete under paving or carpeting, the whole crust of concrete suffers from the effects of street openings and local repairs, but in a greater degree. These difficulties are not insuperable, but they are serious, especially as regards country roads.

The use of reinforced concrete instead of plain concrete as the strength crust for city streets, with asphalt or wood-paving, is a matter quite apart from its use as the strength *and wearing* crust, and it is probable that a considerable amount of such work will be carried out. Where frequent openings of the road are inevitable, however, it seems to present the difficulty that although, with suitable tools, it is easier to cut through 6 ins. of reinforced concrete than 10 ins. of plain concrete, the problem of making good the opening is more troublesome.

Recent Costs.—Concrete roads have been made at the following costs: Southwark, 12*s.* 6*d.* per square yard; Chester, 10*s.* 6*d.*; Dunfermline, 10*s.* 6*d.*; Tilbury, 10*s.* 3*d.*; Dundee, 8*s.* 10*d.* per square yard.

REINFORCED CONCRETE IN ROAD CONSTRUCTION.

(J. F. Butler, A.C.G.I., A.M.I.C.E., M.C.I.)

Reinforced Concrete Foundations for Surfaced Roads.

A reinforced concrete foundation was laid to a road in Manchester in February 1913. Since that time this form of construction has been tested in a number of other towns, and is gradually coming into general use.

The advantages are that great strength is obtained with a small thickness of concrete and that the construction is resilient.

Concrete 6 ins. thick has generally been used with a light wire fabric reinforcement. The reinforcement gives tensile strength to the concrete, and thus provides the resilience, while increasing the strength.

The reinforcing fabric has main wires 3 ins. apart and cross wires 12 ins. apart, and is in rolls 7 ft. wide. It is generally laid with the main wires parallel to the length of the road. It has also been laid with the main wires at right angles to the length of the road, but the other direction seems to be theoretically more correct.

A reinforced concrete foundation is sufficiently strong to spread the heaviest wheel load over so large an area that the pressure on the ground beneath is a very small amount, and not sufficient to cause subsidence even in very bad ground. This method of construction appears to be the most satisfactory and the most economical way of dealing with heavy traffic, and is now extensively used.

Reinforced Concrete Roads.

Complete concrete roads are now very largely used in the United States. The area constructed during 1909 was less than 400,000 sq. yds., and the area constructed during 1914 was about 19,000,000 sq. yds. The annual area from 1914 to 1918, in spite of the reduction of work owing to war conditions, has been rather more than 20,000,000 sq. yds., and figures from 1919 onwards are considerably greater.

The construction has been in most cases adopted after careful investigation as to the success of the existing roads.

In some cases plain concrete is used, in other cases it is reinforced. The latter construction is now more general as it allows the joints to be placed farther apart, in addition to increasing the strength of the road.

In the unreinforced roads, transverse joints are placed about 30 ft. apart to allow for expansion and contraction. They are an absolute necessity, but unfortunately are a source of weakness in that they provide the starting-point for fracture of the surface.

In the reinforced roads expansion joints are placed a greater distance apart, and in many cases they have been omitted altogether with entirely successful results. It appears that they are not necessary if reinforcement is used, and particularly if the surface is coated with tar spray and granite chips.

The subsoil is well drenched before laying the concrete, and on clay ground 2 ins. or 3 ins. of ashes are rolled in to provide a certain amount of drainage.

Usually the concrete is 6 ins. thick and the reinforcement is wire fabric or steel mesh.

The concrete is mixed in the proportion of 3 parts broken stone, $1\frac{3}{4}$ parts sand, and 1 part Portland cement. The broken stone is graded to pass a $1\frac{1}{2}$ in. ring, and the sand is graded from $\frac{1}{4}$ in. down to dust.

The surface is finished by use of a wooden float. It is the latest practice to squeeze the excess water out of the concrete by rolling it with a light roller in the direction at right angles to the length of the road. The roller is made from sheet iron about 6 ft. long and 8 ins. diameter, and weighs rather more than $\frac{1}{2}$ cwt. After the excess water has been squeezed out in this way the surface is further finished off by pulling a belt across it, the belt being worked by a man at each side of the road and being moved with a combined transverse and forward movement. The belt is an ordinary canvas or rubber belt about 8 ins. wide. The concrete is protected from too rapid drying by use of tarpaulin or other covers for 24 hours, and then 'cured' for 10 to 14 days by regular watering, a 2 in. layer of sand or similar material being laid on top to hold the water.

Drainage of town roads is provided in the usual way and country roads are drained by means of effective side ditches.

The length of time for keeping the road closed to traffic depends on weather conditions. The minimum is 14 days in warm weather, but may be much longer if hardening conditions are unfavourable.

The average maintenance cost of concrete roads in the United States is $\frac{1}{2}d.$ per sq. yd. per annum. It is probably better to tar-spray the roads once a year at a cost of about $1\frac{1}{2}d.$ per sq. yd. per annum (pre-war figure).

Concrete road surfaces are ideal for suburban side streets and for secondary country roads. They are also proving suitable for heavy motor-lorry traffic on shod wheels, and they are undoubtedly successful for any kind of traffic on rubber tyres.

The advantages of concrete roads are economy in first cost, economy of maintenance, freedom from dust in summer and from mud in winter, absence of side slip, and the provision of an agreeable running surface.

BRICK ROADS.

(By Alfred B. Searle, Author of 'Clays and Clay Products,' etc.)

Bricks used for roads should be so hard and tough that they will resist the crushing, vibration and abrading actions of the traffic. They must be made of suitable materials, such as marls and shales, which yield a dense, heavy and impervious product when burned. The clays used for common building bricks are quite unsuitable, being too readily disintegrated. Bricks for roads should consist of a tough skeleton, the interstices of which are filled with a tough slag-like mass of great viscosity when molten. When broken, such bricks show a dull, glassy structure, not readily affected by vigorous blows from a hammer. The modulus of rupture R should be at least 1,500 lbs. per sq. in. It is determined by supporting a brick on two knife edges 1 in. apart, and applying a pressure or load of W lbs. by means of a central knife edge. If the brick is b in. wide and d in. deep,

$$R = \frac{3Wl}{2bd^2}.$$

As bricks vary considerably, the test should be made on at least six bricks. When ten bricks are placed in a rattler with 10 cub. in. balls each weighing $7\frac{1}{2}$ lbs. and 245–260 smaller balls of 1 lb. each (making a total of 300 lbs. of balls) and the rattler is rotated 1,800 times at 30 revs. per min., the pieces of brick more than 2 ins. diameter should not weigh less than 75 per cent. of the original weight of the bricks.

The size of bricks used for roads is of minor importance, provided that all the bricks used on a job are sufficiently uniform, i.e., with a variation of not more than $\frac{1}{2}$ in. in length and $\frac{1}{4}$ in. in depth and width. The size usually preferred is 9 ins. by $4\frac{1}{2}$ ins. by 3 ins.

The best results are obtained by using bricks with lugs (A, A, figs. 1 and 2) and a double bevel or bulge of $\frac{3}{32}$ in. at each end to ensure a joint at least $\frac{3}{16}$ in. wide at the top and the bottom

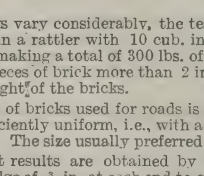

FIG. 1.

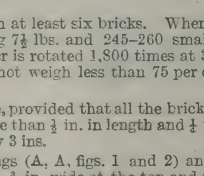

FIG. 2.

of the brick. These are no more expensive to make and they 'key' better than plain bricks. *Pressed* bricks should not, as a rule, be used for roads, as they are less durable than those made by the wire-cut process. Bricks should be laid with the rough, wire-cut sides vertical and in contact with the filler so as to ensure the latter being retained properly. This is almost impossible with the smoother surface possessed by pressed bricks.

CONSTRUCTION OF THE BRICK ROAD.

The *bricks* must be specially made for the purpose, and should possess the characteristics mentioned above. They should be gauged to ensure uniformity in size and their appearance should indicate that they have been uniformly burned.

The *foundation* of the brick road must be good and well drained. A 1:3:6 concrete foundation 6 in. thick is best, but an old macadam road, if well graded and rolled, is satisfactory.

The *cushion* or *bedding course* may be of (i) sand, (ii) sand and dry Portland cement, or (iii) mortar. A *sand bed* should not be more than $2\frac{1}{2}$ ins. thick and consist of uniform grains, and the sand used must be quite dry. It may be consolidated by rolling under a pressure of 15 lbs. per sq. in. A *cement-sand bed* should consist of 1 part of dry Portland cement to 3 parts of sand, well mixed in a dry state and spread on the foundation to a thickness of $\frac{1}{2}$ in., any surplus material being removed with a straight-edge. This bed must not be rolled. The bricks are laid dry on this cushion and are then saturated with water so as to cause the cement beneath to set. This kind

of cushion is better than a plain sand bed, as sand tends to leak away, but it is inferior to a good mortar cushion. A *mortar bedding course* is the best, but cannot easily be used on very steep inclines. The mortar should consist of a 1:4 cement-sand mixture made into a soft paste with water, which is laid on the foundation and well tamped with a tempering strike to consolidate it and give it the required camber. The bricks are laid on this cushion before it has had time to set and are then rolled. By this means the mortar is forced up between the bricks to a height of about $\frac{1}{4}$ in.

If the work is done expeditiously, the surface of the road will be much smoother than when either a sand or dry cement and sand cushion is employed; it will retain its surface indefinitely. The road will emit less noise when traffic passes over it, as the cement-mortar will not shrink materially nor form hollow portions which act as sound-reflectors. A road with a cement mortar cushion is practically monolithic, as the bedding course is really the top of the concrete foundations, and this is united firmly to the bricks above it, forming a 'beam' of much greater strength than when a sand cushion is used. Consequently, a much thinner foundation or sub-grade may be used and the cost of the road is correspondingly reduced, the actual saving being about 4*d*. per sq. yd.

Moreover, a considerable amount of time is saved in constructing the road, as there is no waiting for concrete foundations to set, as is the case when a sand or other dry cushion is used. Hence the cement-mortar or fine concrete bedding course is by far the most satisfactory.

The *bricks* should be laid with their lengths across the road, except at the intersection of two roads where this arrangement may be replaced by a diagonal one, the rectangular area common to both roads being divided into four equal rectangles and the bricks in these laid parallel to the diagonal of each rectangle.

Where one road meets another forming a T, the bricks in the upper part of the road common to both horizontal and vertical portions of the T should be laid as though the road were straight, whilst those in the lower portion of the common part of the road should be laid in a double diagonal.

The bond of the bricks should be made with half bricks; smaller closers should, whenever possible, be avoided.

When laying the bricks, they should be brought smartly against each other so as to effect a good fit with a thin joint. A skilled road layer will not need to use a mallet to drive home the bricks, but less competent men may require to do so occasionally. The courses may be straightened, when necessary, by placing a piece of timber in front of the bricks and striking it with a sledge-hammer until the bricks are driven into position. This treatment is not desirable, except as a means of reducing the bad effect of poor workmanship.

After a sufficient portion of the road has been laid, it should be watered with a hose and the damaged portions and soft bricks (the latter being easily recognised by their dryer appearance) marked for removal. After the bricks have been replaced, the road is rolled across and along in both directions so as to bed the bricks properly. Portions which cannot be effectively rolled should be tamped with an iron-shod rammer. The rolled portion of the road should be tested to ensure the surface being uniform, and any depression exceeding $\frac{1}{4}$ in. should be relaid. The spaces between the bricks should be examined, and if the cushion material has been forced up more than $\frac{1}{2}$ in. between the bricks that portion of the road should be relaid.

The bricks should next be wetted thoroughly, care being taken not to allow much water to pass between them.

The *joints* should be filled with a 3:4 mixture of Portland cement and sand, the latter passing completely through a No. 20 sieve, but being wholly retained on a No. 100 sieve. The cement and sand should be mixed in the dry state, the mixture delivered to the road and mixed with water in a concrete mixer as required. The resultant slurry should be received in spouted cans and poured from these in a thin stream between the joints of the bricks, the fluid being well brushed into the joints. Two or even three applications of slurry may be needed, and are better than filling the joints at once. The second and subsequent quantities of slurry should be more viscous than the first one, and between each application any surplus slurry should be pushed (not drawn) into the joints with a rubber squeezer. The men should not walk or stand on the finished roadway when at work.

Maturing is effected by covering the road with sand which is kept well wetted for several days, so as to allow the cement to set properly. If this precaution is not taken the cement will be weak through a deficiency of water. The sand then may be allowed to dry, after which it can be used on another section of the road.

The road should not be used until three weeks after filling, as if the grouting is disturbed before it has hardened sufficiently the joints will be weak and the road will not be durable. If a road must be open for traffic in a much shorter time, a cement filling is little or no better than plain sand which is merely brushed into the joints, a small surplus being left on the surface of the road to be worked into the joints by the traffic; or a hot mixture of tar and sand may be poured into the joints. If time is less important, the cement-filled joints are far the best.

The *cost* of making brick roads depends largely on local conditions, and the present abnormal cost of labour makes close estimating impossible. Assuming bricks are sold at 5*l*. per thousand

delivered to a station a mile from the proposed roadway, and that the cost of cartage from the station to the site is 6*s.* per thousand, the costs of constructing the road will be approximately :—

Sub-Foundation.	Pence per sq. yd.	Concrete Foundation and Cushion, 7 ins. thick.	Pence per sq. yd.	Bricks.	Pence per sq. yd.
Rough filling at 1*s.* 3*d.* per cub. yd.	6	Labour at 1*s.* 3*d.* per hr.	4	Cost of bricks on site	43
Surfacing and rolling	4	Cement at 6*s.* per barrel of 376 lbs.	14	Laying (piecework)	3
		Gravel at 6*s.* per cub. yd.	8	Rolling bricks	¼
		Sand at 6*s.* per cub. yd.	7	Relaying	¼
		Coal and water	1	Filler for Joints.	
				Cement at 6*s.* per cub. yd.	3
				Administration and Miscellaneous Expenses.	3
Total per sq. yd.					8*s.* 1*d.*

If a sand cushion is used instead of a cement-sand mortar one, the cost will be increased by about 2½*d.* per sq. yd.

If an old macadam road (after grading and rolling) is used as the foundation, the cost of the brick road would be reduced by about 1*s.* 1*d.* per sq. yd.

These figures are purposely liberal and can probably be considerably reduced in the near future.

Nature of Pavings used in London.

(Based on the Metropolitan Paving Committee's Thirteenth Annual Report for 1915 and previous experience.)

The London area offers a favourable field in the study of street pavements. The climate does not approximate to any of the extremes of the British Isles, the gradients are variable, but seldom very steep, and the market for materials is a good one. The traffic conditions which have to be faced include heavy dock traffic, very busy city traffic, that of residential roads, motor omnibus routes, and the great main roads leading to the country. Lastly, the reports of the Metropolitan Paving Committee provide the materials from which deductions can be made as to the value and importance of different pavements, and including comparisons as to wearing qualities and costs.

Creosoted Softwood.—Creosoted softwood, chiefly deal and fir, is largely employed, especially for main thoroughfares, and continues to prove satisfactory. In the earlier work a 6-in. 'foundation' of Portland cement concrete was usually provided, but this thickness is not now found sufficient for heavy traffic. Concrete 8 ins. thick is sometimes put down, but for heavy traffic it is usually from 9 to 12 ins. The thickness of the wood-paving is usually 5 ins., but often 4 ins. The blocks are often grouted with pitch, or dipped in a mixture of tar and pitch when they are being laid, but the most usual recent practice is to run the joints with a mixture of hot pitch and creosote oil. The following sizes of blocks are used : length, width, depth ; 9 × 3 × 5, 9 × 3 × 4, 8 × 3 × 5, 8 × 3 × 4.

Hardwood.—Hardwood pavings have proved very lasting, but are being superseded by softwood or other pavings. *Jarrah* has lasted ten years in the Euston Road, very heavy traffic ; 19 years in the Streatham High Road ; 10 to 14 years in heavy traffic thoroughfares in Hampstead ; and in other streets 13 to 17 years, and 19 years. *Karri* has lasted up to 21 years. These woods are inferior to softwoods as regards even wearing, and do not so readily take up the armouring of grit which so greatly aids in preventing slipperiness of softwood pavings. In 1915, *sectional Jarrah* blocks, which seem to be better than ordinary blocks of hardwood, were laid in pitch, on a 9-in. concrete 'foundation,' and in some cases re-cut. Jarrah blocks were re-laid.

Wood-paving is now often laid on a thin layer of asphaltic or bituminous material, between the wood blocks and the concrete.

Asphalt.—Compressed asphalt on a concrete strength crust or 'foundation' is one of the most important heavy traffic pavings in London. The thickness of concrete required varies as in the case of wood-paving, and is practically the same for similar traffic. The thickness of the asphalt carpet is usually 2 ins.

Bituminous layers.—Bituminous materials have been employed, in some cases, as carpeting layers only, but in other cases in crusts of sufficient thickness to take a share in distributing the loads. In 1915, only materials of this kind were used for street surface renewals in *Fulham*, usually 2½ to 3½ ins. of 'bituminous macadam' on a 12-in. foundation of hardcore, the surface

TABLE XIV.—COSTS OF PAVING.

(Pre-war.)

	Marylebone	2	6	—	12*s.* 6*d.*	—
Asphalt	Westminster	2	—	8*s.* 2*d.*	13*s.* 6*d.* to 13*s.* 9*d.*	—
Tar-slag macadam	Holborn	4½	—	3*s.* 5*d.*	5*s.* to 6*s.* 11*d.*	Hardcore foundation.
		3½	—	2*s.* 8*d.*	7*s.* 1*d.*	
Tar-macadam	Marylebone	4½	—	—	3*s.* 5*d.* to 4*s.* 1*d.*	'On an old foundation.'
Sectional Jarrah blocks	Stoke Newington	3	—	—	16*s.*	—

being treated with liquid bitumen and granite chips or with a 1-in. carpet of asphalt. This construction is very interesting, as it embodies (*a*) a wearing crust which partially distributes the load; (*b*) a foundation which is also a strength crust; (*c*) a wide spread on the road bed and low stresses in this crust, these results being obtained by the use of a considerable depth of relatively cheap material; and (*d*) the initial spread of the load by the wearing crust. In *Hampstead*, 'asphaltic macadam' 1½ ins. and 2 ins. thick was laid, and in *St. Marylebone*, 'bituminous pavements' 1½ ins. to 3½ ins., some of these on old macadam crusts. 'Asphaltic graded granite' 3 ins. thick was put down in *St. Pancras*, and 'asphalt macadam,' 4 ins. deep in two layers on existing macadam, in *Woolwich*.

Tar macadam.—The following were laid in 1915. Tar macadam (granite) 3 ins. thick on old macadam; tar macadam 4½ ins. thick; tarred slag macadam, 4 ins. thick on a foundation of hardcore, and 4½ ins. thick on 'an old foundation.' Tar macadam is chiefly used, in London, for light traffic streets.

Stone paving.—Considerable areas were paved, in 1915, with small granite setts, the usual depth being 4 ins.; also Aberdeen granite setts, 4 × 6 ins. on a 12-in. crust of cement and clinker concrete. Re-dressed Aberdeen granite setts 3 ins. by 6 ins. were laid on 6 ins. of concrete; fine dressed 'Norwegian' granite setts were laid in cement and sand grout on 12 ins. of concrete; and setts, 4-in. cubes, laid in 1 in. of ashes and grouted with pitch grout, on a macadam crust.

TABLE XV.—COSTS OF PAVING.

(*Pre-war.*)

(2.)

(*Summarised from the Metropolitan Paving Committee's Tenth Annual Report.*)

Material.	Situation.	Depth in Inches.		Cost per Sq. Yard.		Remarks.
		Paving or Carpet.	Foundation.	Without Foundation.	With Foundation.	
				s. d.	*s. d.*

Tar-slag macadam	Hammersmith	3	—	2 9	—	'On an old foundation.'

SCAVENGING AND WATERING.

Important developments are taking place in the matter of house and street scavenging and street watering. Very considerable savings are effected by the use of motor vehicles instead of horses. For instance, in one Metropolitan borough, a saving of 2,000*l.* is reported as the result of fifteen months' working with motor vehicles. In other cases a single motor vehicle is found to replace as many as six horses, in the case, for instance, of a 3½-ton electric watering vehicle, with a capacity of 750 galls. Petrol motors seem specially suitable for sweeping machines, and there is a healthy rivalry between steam, electric, and petrol vehicles in the field of refuse collection. For the types of vehicles recently purchased, and prices, see 'Costs Data,' at the end of this section. For the latest pre-war costs of cleansing and watering see Table I, p. 706.

The following table of costs is derived from the Metropolitan Paving Committee's fuller tables. The reason for taking the earlier period as well as the year under review is that the effect of surface tarring may be seen. The figures given for surface tarring are not the costs of tarring per mile of tarred road, but are got by dividing the cost of tarring by the whole road mileage in the borough. Even if we include the cost of tarring, the cost of scavenging and watering in Wandsworth and Fulham was considerably reduced, and, taking everything into account, the same tendency may, perhaps, be seen in the cases of Hammersmith and Greenwich. For a full analysis it would be necessary to consider the weather of each year, and the value of the tarring *per se* as well as its effects on the costs of maintenance. (See *The Surveyor*, March 22, 1912.)

APPROXIMATE ANNUAL COSTS PER MILE (WHOLE MILEAGE).

The effects of motor-omnibus traffic and other heavy traffic.—Some years before the war, reports of the Paving Committee showed that heavy motor traffic had increased the cost of maintenance of macadam roads generally. As regards paved streets and roads, the cost of maintenance had increased in those areas in which the stage of strengthening and improvement had been reached, but had increased only slightly or not at all where this stage had been passed. When the cost of reconstruction had been taken into account on the one hand, and actual increases in the passenger-mileage and ton-mileage on the other, it seemed that the economics of road maintenance in London had not been changed for the worse, though the cost of cutting through the greater thicknesses of concrete provided a new argument in favour of the scheme for providing subways for the various conduits under the main streets.

The present day.—Monetary comparisons being for a time almost useless, except where founded on detailed data, we must consider that the position indicated in the foregoing paragraph arises in a fresh form, owing to the increase in motor-lorry traffic, and, probably, an increase in motor-omnibus traffic. The Committee's reports of the next few years will show whether the situation remains as described, and calls only for the extension of measures already taken in some areas or whether further measures will be necessary.

NAMES OF ROCKS USED FOR ROAD METAL.

When a single word is employed as the name of a rock used for road metal or for paving setts the word may be definite in itself, denoting a rock of a particular composition which does not, as a rule, vary much from the average. In other cases, the general word, or word denoting the normal material, is compounded with another word, usually the name of a mineral which is present in an unusually large proportion, or which is an unusual constituent or one of several any of which may be present. Thus, a diabase is usually composed chiefly of labradorite and augite, and sometimes olivine; and dolerite, though different in texture, is similar in composition. An olivine dolerite is a dolerite in which olivine is present in a considerable proportion, and a quartz-enstatite diabase is a diabase in which both quartz and enstatite (minerals, not rock names) are present in noteworthy proportions. The name of a mineral may sometimes be used as the name of a rock in the composition of which it predominates; but usually there is a clear distinction between the names of minerals and those of rocks, which are formed of several minerals. Even when a rock consists almost entirely of one mineral it may have a name which discloses its character. Quartz is the predominating mineral in sandstone and in quartzite.

The mineralogist is sufficiently equipped with his precise nomenclature, which, in some cases, enables him to convey useful information by giving alternative compound names to the same stone. The highway engineer, on the other hand, requires group names as well as particular

names. The following classification was suggested some years ago (*vide* 'The King's Highway' as a tentative grouping. It is here slightly altered.

Granites: True granites, horneblende granites (micro-granites).

Felstones: (*a*) Basaltic felstones:—Basalts, diabases, dolerites.

(*b*) Hornblendic felstones:—syenite, diorite, quartz-syenite, quartz-diorite.

Traps: (*a*) Whinstones—basic traps.

(*b*) Elvans—acid traps, quartz-felsites, quartz-porphyries (micro-granites).

Quartzites: both metamorphic and sedimentary.

Limestones: compact limestones, crystalline limestones.

Rags: calcareous sandstones, siliceous limestones.

Sandstones: true sandstones, grits.

Flints: flints, chert.

Pebbles: large broken pebbles to be named according to their class, small pebbles classed as gravels.

Some Important Words in their Narrower Application.

The following are definitions of certain important rocks:—

Granite.—A coarsely grained, wholly crystalline rock, mainly composed of alkali felspar, quartz, and a ferro-magnesian mineral.

Gneiss.—A metamorphic (altered) rock, usually resembling granite, but showing a foliated or banded structure.

Syenite.—A wholly crystalline rock, composed of orthoclase felspar, a ferro-magnesian mineral (usually augite or horneblende) and a small proportion of quartz.

Diabase.—A compact, dark rock, mainly composed of labradorite, augite, and sometimes olivine; is thoroughly crystalline and often ophitic (ophitic: a structure in which the crystals of one mineral inter-penetrate or are moulded upon those of another).

Dolerite.—Often classed as basalt, or as diabase. (The terms 'diabase' and 'dolerite' are often used synonymously.) Is more crystalline than basalt.

Diorite.—Consists essentially of oligoclase, andesine or labradorite felspar, and horneblende, augite, or biotite.

Basalt.—A black compact lava, basic (alkaline) in character. Consists essentially of plagioclase, augite, and olivine, is sometimes porphyrictic, and often contains uncrystallised glass substance in the ground mass.

Porphyry.—Contains large crystals, usually of potash-soda felspar, in a ground mass of felspar, quartz, and other minerals.

Andesite.—A lava, intermediate between acid and basic, consisting principally of plagioclase, felspar, and ferro-magnesian minerals, usually without olivine.

Quartzite.—Composed almost entirely of close-fitting quartz grains, the cementing material being itself quartzose, distinguishing it from sandstones.

Whinstones.—In its narrower and more correct use the term is applied to dyke or trap rocks. A typical whinstone may be classed as an andesitic dolerite, containing augite, or as a quartz diabase.

THE ROAD BOARD LABORATORY.

(*See Report to the Third International Road Congress, T. E. Stanton and R. G. Batson.*)

The equipment of the Road Board Laboratory (at the National Physical Laboratory, Teddington) enables the following set of tests of road stones to be made.

(1) A dry attrition test (resistance to wear); (2) a wet attrition test; (3) an abrasion test (for hardness); (4) a repeated impact test (toughness); (5) a test of the cementation value; (6) an absorption test.

Attrition test.—The machine is of the 4-cylinder Deval type, as used in France and in the United States. The cylinders are $7\frac{1}{2}$ ins. in diameter and 14 ins. long, set at 30° to the axis of rotation. About fifty pieces of the rock, weighing eleven pounds, are placed in one of the cylinders, and the machine revolved 10,000 times at about 30 revolutions per minute. Only the material which will pass a sieve of $\frac{1}{10}$ mesh is counted in measuring the amount of wear, which is recorded both as a percentage and by the French coefficient $\frac{40}{\text{percentage of wear}}$.

In the wet test 1·1 gallon of water is used with 11 lbs. of stone. The wear is usually greater in the wet than it is in the dry test; but not always.

Repeated impact test.—This test is made with the Page impact machine, which has a hammer weighing 4·4 lbs., delivering the blows through a plunger, the surface of which, in contact with the specimen, is spherical to a radius of 0·4 inch. The test piece is a cylinder, 1 in. by 1 in., ground to the true diameter, and cut to length by a diamond saw. The test consists of a series of blows, beginning with a fall of 0·4 inch, which is increased by 0·4 inch with every successive blow until the test piece is broken. The toughness is measured by the number of blows. Tests can also be made with a constant height of fall.

Abrasion test.—The test piece is prepared in the same way as for the impact test and is of the same size. The machine is of the Dorry type, and consists of a cast steel disc revolving in a horizontal plane. The test piece is held, with its axis vertical and with a load equal to 3·5 lbs. per square inch, against the surface of the disc 26 cms. from the centre. Standard sand of 30 to 40 mesh is fed continuously through funnels at a definite rate, the same in each case. After about 1,000 revolutions of the disc, at the rate of 28 per minute, the test piece is weighed and the loss of weight noted. The test is repeated on the other end of the test piece, and the average loss of weight by the two runs is recorded. The hardness is measured by $(20 - \frac{1}{3}W)$ where W is the loss of weight in grammes per 1,000 revolutions.

Cementation test.—Coarsely crushed rock, weighing 1·1 lb., is ground in a ball mill with 0·02 gallon of water, the balls being steel shots (two) 5·1 ins. in diameter. The material is ground for two and a half hours at the rate of about 2,000 revolutions per hour. The resulting paste is moulded into briquettes, 1 in. diameter and 1 in. long, the maximum pressure being 1,880 lbs. per square inch. After twenty-four hours, the briquette is dried for twenty hours in the air, and for four hours in a hot air bath at 200°F., cooled for twenty minutes in a desiccator, and then tested. It is placed on the anvil of the machine, with its axis vertical, and struck through a plunger by a small hammer with an effective drop of 0·4 in., the rebound being measured by the movement of a lever attached to the hammer, and holding a pencil against a paper-covered revolving drum. This records the number of blows required to destroy the resiliency of the test piece, after which there is no rebound. The mean of six tests is taken as giving the cementing value of the material.

Specific gravity.—Three samples are taken from each batch of stones, and the average specific gravity recorded as that of the batch.

Absorption of water.—A stone of about 13 lbs. is weighed in air and then in water. It is kept in water for three days and is then weighed in air. If A=weight in air, B=weight in water immediately after immersion, and C=weight in water after immersion for three days, the number of pounds of water absorbed per cubic foot of rock is nearly

$$\frac{C - B}{A - B} \times 62{\cdot}5.$$

Petrological analysis.—The classification of the rock, in the terms of geological nomenclature, and as regards its constituents, is made for the Road Board at the Geological Museum (Director, J. Allen Howe).

Road Board Laboratory Report, 1914–1915

During 1914–1915 the Road Board Laboratory was occupied with mechanical tests on stone for road construction, and with tests made by the special testing machine on roads formed with different varieties of asphalt carpets laid on a concrete foundation.

Micro-sections of the roads tested were made at various stages, and one road in particular furnished results showing the utility of the microscope in the study of road construction problems. Three different sections of the road were examined—(1) a portion as laid down, before the test was started; (2) a portion after the completion of the test, taken from a place where the road was still in good condition; and (3) a portion where, after the test, the road was in bad condition. From each specimen a small piece was cut at right angles to the surface of the track and carefully polished; this permitted a study of the structure both close to the surface and in the interior. The road in question contained 55 per cent. of $\frac{3}{8}$ in. granite, the rest of the mineral matter being of smaller grading. On the surface there was a carpet composed of bituminous and fine mineral matter, approximately $\frac{3}{8}$ in. thick, all the large granite lying below this carpet, which appeared to take the whole work of the road; if it was penetrated or removed the road began to disintegrate rapidly. In the section which was in good condition at the end of the test, the structure was found to be identical with that of the road as first laid down; but in the portion that was in bad condition the $\frac{3}{8}$ in. granite chips were visible in the surface.

A section of another road that broke up a few hours after the beginning of the wet test, in which the whole surface was covered with water, showed on analysis a very low percentage of bitumen; when a similar road was laid down with a much higher percentage of bitumen, it stood the water test for 14 days. This appears to show that with a certain grading there is a limiting percentage of bitumen which will make the road resistant to water action, though a much lower percentage of bitumen will enable it to resist the same traffic in a dry state.

COSTS DATA.

Cost Calculations: Creosoted Deal.

From a report by Mr. H. T. Wakelam, M.Inst.C.E., county engineer for Middlesex, who relaid several lengths of creosoted deal paving which had been down for fourteen years to eighteen years in Middlesex. Mr. Wakelam takes as a basis on comparison an annual cost of 1*s.* 4¾*d.* per sq. yd. for a fifteen years' life of a bituminous road, finding the cost of creosoted deal to be 1*s.* 1¾*d.* per annum for a fourteen years' life, as follows :—

COST OF CREOSOTED DEAL PAVING.
(Pre-war.)

(*H. T. Wakelam.*)

	£ *s.* *d.*	£ *s.* *d.*
Area (say), 5.000 sq. yds.		
Cost, 11*s.* 9*d.* per sq. yd.—		
Wood, at 7*s.* 6*d.*	1,875 0 0	
Concrete, at 4*s.* 3*d.*	1,062 10 0	
		2,937 10 0
Half-yearly instalments on loan :—		
Wood, 10 years at 3¾ per cent. per annum	113 5 9	
Concrete, 20 years at 3¾ per cent. per annum	37 7 0	
		150 12 9
Annual repayment for wood (10 years)		226 11 6
Annual repayment for concrete (20 years)		74 14 0
Total repayment for wood	2,265 15 0	
Total repayment for concrete	1,494 0 0	
Total repayments for wood and concrete		3,759 15 0

	s. *d.*	*s.* *d.*
Cost per super. yd. for wood (including interest) for period of loan (10 years)	9 0·756	
Cost per super. yd. for concrete (including interest) for period of loan (20 years)	5 11·712	
Total cost of wood and concrete (including interest)		15 0·468

	d.	*s.* *d.*
Cost per super. yd. per annum for wood for period of loan	10·875	
Cost per super. yd. per annum for concrete for period of loan	3·585	
Total cost of wood and concrete per sq. yd. per annum for 10 years		1 2·460

	d.
Cost per super. yd. per annum for wood for 14 years	7·768
Add concrete	3·585
Add maintenance	2·500
Total cost per yard per annum for 14 years (including repayments of principal and interest)	13·853

	s. *d.*
Cost of relay of wood (including interest) for second period of 14 years	9 0·756
Balance of cost of concrete, 6 years at 3·585*d.* per yard per annum	1 9·510
Total cost of relay (including interest)	10 10·266

	d.
Cost per super. yd. per annum for wood for 14 years	7·768
Add concrete	1·536
Add maintenance	2·500
Total cost per yard per annum for second period of 14 years (including repayments of principal and interest)	11·804

Road Crust Work.

Labour.—Northamptonshire, about twice pre-war rates. Consolidation of road metal, 1*s.* 3½*d.* per ton. Dorset, labourers 1*s.* 1*d.* per hour. Labour generally about twice pre-war rates. Blyth, 9*s.* 8*d.* per man-day.

Road metal.—Staffordshire, 1918–1919. Road metal at roadside, 15*s.* to 20*s.* per ton; road metal supplied, usually, 14*s.* per ton. A coating 3 ins. thick with bituminous grouting, 2*s.* 8*d.* to 3*s.* 3*d.* per square yard.

Bituminous clinker.—Single coat, 6*s.* per sq. yd.; two coats, 8*s.* 7*d.* per sq. yd., 1918.

Steam rolling.—Kent, steam roller, 38*s.* per working day, 15*s.* per standing day. Blyth, 2·29*d.* per sq. yd.

Reconstruction.—County of Nottingham, main road reconstruction, 1918–1919, including a central portion made up with 'Tarmac,' and sides strengthened with slag and granite, 114 miles, of which 24 miles were urban. Cost, 1,563*l.* per mile.

Analysis of cost of 'Tarmac' (Blyth, 1919).—Labour, 3·57*d.*; rolling, 2·27*d.*; cartage, 4·49*d.*; stone, 23·47*d.* Total, 33·82*d.*, or nearly 2*s.* 10*d.* per square yard. The 'duty' was 8½ sq. yds. per ton of material. Labour cost 9*s.* 8*d.* per man-day; cartage, 17*s.* per cart-day; 'Tarmac,' 18*s.* 7*d.* per ton.

Surface Tarring.

Costs per square yard, 1918–1919.—Northamptonshire, 1·97*d.*; East Suffolk, 2·1*d.*; Nottinghamshire, 2·26*d.*; Essex, 2·5*d.*; Blyth (Northumberland), 2·5*d.*, with tar at 18*s.* 4*d.* per barrel. Usually about 2·5*d.* per sq. yd., including spreading with chips.

Costs per mile.—City of Lincoln, including sanding, 131*l.* per mile; tar used, 2,950 galls. per mile. Norfolk county main roads, 92*l.* per mile.

Horse Haulage.

Staffordshire, 1918–1919.—Cartage of road metal, usually 3*s.* per ton to the roadside.

Northamptonshire. 1918–1919.—Haulage, 150 to 200 per cent. over pre-war rates. Horse and cart, 20*s.* a day.

Kent.—Horse and cart, 15*s.* to 18*s.* a day.

Midland Railway.—Cost of upkeep of a horse, 1917, 27*s.* a week; 1918, 34*s.* a week.

Nottinghamshire, 1919.—2*s.* per ton mile.

Blyth.—17*s.* per cart-day.

Public Service Vehicles Prices, 1919.

Steam Wagons.—Cardigan County Council, 1,295*l.*; Foden wagon, 1,260*l.*; Clayton wagon, 1,260*l.*; side-tipping wagon, 5-ton, rubber wheels, 8 miles an hour, Clayton and Shuttleworth, 1,290*l.*; end-tipping wagon, 5-ton, Robey, 1,080*l.*

Petrol Vehicles.—Motor-lorry, 1,000*l.*; motor-wagon, 1,000*l.*; motor-lorry, Leyland, 1,080*l.* (Many motor-lorries have been bought second-hand from the War Department, so there have not been many purchases of new vehicles by local authorities.) Motor fire-engine, 1,445*l.*

Electric vehicles, house refuse collection.—2½ ton, Garrett & Co., for Harwich Town Council, 1,175*l*; type unspecified, 25 vehicles at 1,280*l.* each; British Edison, 1,307*l.*

Electric scavenging vehicles.—Type unspecified 1,284*l.*; 'dust cart,' 1,667*l.*

Working Costs, Motor Omnibuses.

Sheffield.—The omnibuses run on a number of routes within the City of Sheffield, 15 miles, and as extensions of tramway routes outside the city, 22 miles, on County Council roads. There are about 40 omnibuses, of which 26 are Daimlers and 12 A.E.C. About 30 are double-deck and 10 single-deck. The maximum seating capacity is 37. The minimum weight of a suitable omnibus has been found to be 4½ tons.

Average expenses per bus-mile, 17·9*d.* Service of debt (capital), 0·9*d.* nearly. Total, 18·8*d.* nearly. Working expenses per passenger, 2·25*d.* nearly; per seat-mile, 0·56*d.* Average fare per mile, 1·5*d.*

Working Costs, Steam Wagons.

Nottingham County Council.—Three steam wagons, one Burrell, one Clayton No. 1, one Clayton No. 2, each with two trailers, bought 1915, 1916 and 1918. Cost, 2,576*l.* 10*s.* Working expenses, 1918–1919, nearly 1,145*l.*; depreciation, 12½ per cent., 244*l.* 17*s.* Cost per day, 2*l.* 9*s.* 8½*d.*; per mile, 4*s.* 9*d.*; per ton mile, 7·4*d.*

Herefordshire.—Cost of working, 404*l.* per annum; chief items, wages of driver and steersman, 181*l.*; depreciation, 103*l.*

Working Costs, Electric Vehicles.

Kettering Urban District Council (W. A. Walker, A.M.I.E.E., Electrical Engineer).—3½-ton, G. V. Electric vehicle; iron-clad exide battery; annual cost of working, including capital charges and depreciation, 785*l.*; chief items, wages, driver and mate, 410*l.*; battery upkeep, 100*l.*; repairs, oil, etc., 97*l.*; current at 2*d.* per unit, 50*l.*; mileage, 4,392; cost per ton hauled, 1*s.* 11*d.* Two years' working, very satisfactory.

Hampstead.—3½-ton Orwell electric tipping vehicle; iron-clad exide battery; estimated annual cost of working, including capital charges and depreciation, 502*l.* Chief items, wages, driver, 200*l.*; depreciation, 82*l.*; battery upkeep, 70*l.*; current at 2*d.* a unit, 52*l.*

SECTION XV

ARRANGEMENT AND CONSTRUCTION OF ENGINEERING WORKSHOPS — WORKSHOP PRACTICE — DEPRECIATION OF PLANT AND MACHINERY

(With Contribution by H. N. Allott, M.Inst.C.E.)

SECTION XV

ARRANGEMENT AND CONSTRUCTION OF ENGINEERING WORKSHOPS — WORKSHOP PRACTICE — DEPRECIATION OF PLANT AND MACHINERY

ENGINEERING WORKSHOPS.

(Contributed by H. N. Allott, M.Inst.C.E.)

For ordinary engineering purposes the arrangement of shops on one level is most convenient, as this allows of better supervision, better access between the various shops, and better light than is possible where the works are arranged in buildings of more than one storey. Multiple storey buildings are generally only used in cases where the work and the machinery are of a light description and where the cost of land outweighs the increased cost of buildings and the advantages of the single-storey shop.

It is advisable to arrange the position of the office buildings so that the entrance or exit to offices and works, both for persons and goods, may be controlled from one time and enquiry office. For small work where heavy cranes are not required, and where the type of machinery employed is small, the saw-tooth type of roof will be found most convenient; whilst for shops where the machines and the work are of a heavier description, and the spans consequently greater, a ridge roof is the best arrangement.

Figs. 1 and 2 show typical buildings comprising heavy machine and erecting shops, together with light machine and fitting shops.

The heights shown in the buildings are 30 feet for the erecting and heavy machine shops and 15 feet for the light machine and fitting shops. It will be noted that the roofs of all the bays are of the ridge type. The smaller bays of roofing are also of this description, since saw-tooth roofing should not generally speaking be of a greater span than 25 feet.

The widths of the bays depend on the machines employed and the character of the work to be carried out, and where these matters can be arranged to suit a bay of not more than 25 feet in width a roof of the saw-tooth type is undoubtedly the best. If the bays are of a greater width than 25 feet, the increased length of the glazing bars necessitates the use of a centre purlin and also increased strength in the rafter back.

The arrangement shown in figs. 1 and 2 is laid down on the supposition that the flow of work in the small machine bays will be parallel to the line of the larger bays, the machines and cranes where required being arranged in lines in this direction.

The roof principals are arranged at right angles to the length of the shop, so that the shafting, heating, and lighting pipes may be conveniently carried from them, and the span of the roof is accordingly 30 feet. Should, however, the character of the work to be carried out make it convenient to arrange the machines and cranes in the smaller bays at right angles to the length of the shop, the roof principals for the smaller bays will run in the contrary direction, and the span would be reduced to 25 feet, when a saw-tooth roof may be used with advantage. In tropical countries the use of saw-tooth roofing is almost compulsory as the rays of the sun are almost vertical.

Saw-tooth roofing where possible is usually arranged with the glazing facing north so as to prevent the direct glare of the sun through the glass. The principal advantage of the saw-tooth roof is that by its use a more evenly lighted and cooler shop is obtained.

The amount of glazing to be allowed for in a roof of the ridge type should be not less than about 50 per cent. of the area of covering, and in town districts with a smoky atmosphere this may be increased with advantage to 60 per cent. or 70 per cent.

The glass should be equally distributed on both sides of the roof, as by that means a more even illumination is obtained than when all the glass is placed on one side of the roof.

Another advantage of distributing the glazing is that the direct glare of the sun and consequent heating of the shops in summer is minimised.

FIG. 2.

The roof covering in this country usually consists either of slates, asphalt felt, or corrugated iron.

For slates or corrugated iron the roof generally is given a rise of not less than quarter of the span, for if made of a flatter slope rain and snow are liable to blow in at the joints.

For felted roofs the roof may be practically flat if the joints are properly made with mastic and it is only necessary to give a fall of one or two inches to the foot to allow for drainage.

Galvanised corrugated iron is usually only used in this country for buildings required for temporary purposes, and when used should be carefully painted before and after fixing, and afterwards properly maintained, as otherwise its life is only short.

Slating, when used, may be laid on battens nailed to spars, or to boarding nailed to the purlins. When laid on spars the slates should be pointed on the underside with hair mortar. When laid on boarding the boarding should be covered underneath the slates with sarking felt.

An alternative to natural slates is the use of asbestos slates. These are best laid either with the diagonal parallel to the slope of the roof, or in what is termed 'honeycomb' fashion. The point of the slate should be cut off, as it is otherwise liable to be broken by any one walking on the roof. It is necessary in all cases to see that proper lap is given to the slates, and this is especially the case where asbestos slating is used, as owing to its smooth surface the roof is more liable to leakage, where proper attention is not given to this.

An alternative to galvanised corrugated iron sheeting is the use of corrugated sheets of asbestos composition, which can be obtained up to 10 ft. in length and 27½ ins. in width.

Asphalt felt laid on thicknessed, grooved, and tongued boarding is cheaper than slating and is not damaged like slating by men walking on the roof.

The use of felt of good quality is permitted by the building departments of most local authorities, although one or two treat it as not being sufficiently incombustible.

The felt is laid in mastic and nailed to the boarding, the joints being lapped about 4 ins. One thickness of stout felt will make a satisfactory job, if properly laid and if proper attention is given to maintenance, though the roof is generally covered with an extra thickness of a thinner quality of felt where a thoroughly good job is required. One advantage of the use of felt is that a considerable saving can be effected by forming the gutters in felt, instead of using cast iron gutters; this is especially the case in roofs where large valley gutters are required. A considerable amount of lead required for flashing at various parts of the roof can also be saved.

The only attention required to be given to felted roofs is a coat of varnish at intervals of about five years.

The roof glazing is best carried out with patent glazing, the alternatives to patent glazing being wood or tee steel glazing bars, the glass being puttied in.

The patent glazing is preferable, as with puttied bars the putty becomes defective and the glazing leaky, unless systematic attention and painting is given.

The best systems of patent glazing consist of a steel bar, to which is fixed a lead flashing, which is worked down on to the glass to form a weather-tight joint.

In most cases the glazing bar is sheathed all over in a lead casing, the ends of which are soldered up, thus obviating the necessity of painting. The bars should be galvanised before the sheathing is put on. Except in the case of vertical or steep-pitched glazing, as in the case of a saw-tooth roof, it is not advisable to joggle the glazing bar to form a lap in the glass. If this is done on a flat-pitched roof leakage is liable to occur, owing to capillary attraction between the two panes of glass. Where it is necessary to form a joint in the glazing on a roof of ordinary pitch, it is better to step the glazing bars.

The roof glazing is best carried out with wire wove glass, which holds together and does not drop if a pane is broken.

In a machine shop the number of cubic feet of air space is generally sufficiently large, in comparison with the number of men employed, to render extensive roof ventilation unnecessary, and sufficient ventilation may be provided by opening sashes in the glazing to a saw-tooth roof, or by ventilators at intervals along the ridge in the case of a roof of the ridge type.

The ventilators for a ridge roof to a machine shop are best provided with opening shutters so that the ventilation may be stopped in the winter or in driving rain or snow if required, or if preferred, exhaust ventilators can be used.

In the case of a foundry it is usual to provide ventilators with continuous louvres for the whole length of the shop. These are best made of wood with a rebated fillet screwed on the back to stop rain or snow from driving in as far as possible.

The roof principals are best formed in steel of angles, tees, and other rolled sections. A steel principal offers less obstruction to the light and harbours less dust than a timber principal, and can generally be designed at very little greater cost, if any.

For roofs of moderate span up to, say 50 feet, economical spacing may be taken as from 10 feet to 12 feet, which allows purlins of angle section to be employed. For roofs of larger spans it is frequently more economical to space the roof principals farther apart, and to use purlins of channel, zed, or rolled joist sections.

It is usual to arrange the roof so that the purlins are carried at the panel points of the truss, i.e., at the intersection points of the rafter with the other members. If this is not done the strength of the rafter back must be increased to provide for the bending moment due to the load coming on to it from the purlin, in addition to the compression due to the internal stresses in the framing of the roof principal itself.

A factor of safety of 4, which is equivalent to a tensile stress of about 7 tons per square inch, is commonly used for buildings of a permanent description. In the case of buildings where a long life is not required this figure may be increased to 9 tons per square inch.

The stanchions and girders carrying the roof and gantries are now commonly made of steel of various sections in place of cast iron as in the older shops. A steel stanchion can usually be designed more economically than one of cast iron, is not so liable to damage from blows, and attachments can more easily be arranged for girders to carry shafting, jib cranes, etc.

Round cast-iron columns are sometimes used to carry the roofing of small spans for light machine shops, and light foundries where cranes are not required.

In cases where the crane loads and lengths of the stanchions permit, cheap and convenient forms are provided by the use of rolled steel joists of suitable section, with flat bars or steel channels riveted on to give additional flange area (figs. 3, 4, and 5). The section formed of a rolled steel joist and two channels is a very convenient one, and allows of the easy attachment of brackets, etc., in both directions.

FIG. 3.

FIG. 4.

FIG. 5.

Types of Compound Stanchions to carry Light Cranes or for Multiple Storey Buildings.

Where the shafting is carried from the crane girders, as is sometimes the case, the deflection and stiffness of the girders under load must be inquired into to ensure that the proper running of the shafting is not interfered with.

The economical spacing of the stanchions is determined by the total cost of the stanchions and foundations and the girders carried by them, but this must also in many cases be affected by the spacing of the machinery. In the small machine bays the tools will usually be arranged in long rows parallel to the lines of stanchions and the width of the bay will be a sum of the machine widths and alley ways. The spacing of the stanchions longitudinally will, however, not be affected by the machines, as these will usually be clear of the line of stanchions. For light work, bays arranged with the stanchions placed in squares of 20 feet will usually be suitable and economical in structural cost.

In the case of the large machine bays, the details of the machines will affect the centres of the stanchions longitudinally, as it will be frequently necessary to arrange for these to be placed partly between the stanchions. The width of the bay will be determined by the depth taken by the machines and the space required for assembling work and storing material. The spans and widths of bays shown will be generally convenient for a shop doing ordinary engineering work, but each case requires consideration and should be decided on its merits.

Provision must be made to carry the shafting on the stanchions for the larger bays, where the machines are not independently driven by motors. This is most conveniently arranged for by fixing four longitudinal channels braced together or two rolled steel joists at a convenient height.

The stanchions should be stayed transversely by knee bracing, or by lateral bracing, along the plane of the bottom member of the roof principals. In the case of very high buildings it may be necessary to use both methods.

The roof should also be braced diagonally along the planes of the rafters at the ends of the building, and in the case of very long buildings at intervals in addition.

The foundations for the stanchions and walls are best constructed of cement concrete, mixed six to one. No bedstones are necessary for the stanchions, which can be wedged up to the required level, and grouted with cement and sand in equal proportions. It is advisable to have one or two holes drilled in the stanchion base to vent same, and so allow of the escape of air when grouting. The walls are best constructed of brickwork, in hydraulic lime mortar, or may be framed and constructed of reinforced concrete, about 3 ins. to 4 ins. in thickness.

By the use of special metal lathings, which can be plastered on both sides with cement mortar, it is possible to obtain a weatherproof material with a thickness of 2 ins. If this material is used, a waterproofing medium should be added, in mixing, to the mortar for the outer covering.

This latter method of construction is specially applicable to the filling in to the sides of the main bay, above the roof of the small machine shop, and to the ends of ventilators. It may be also used for a roof covering, where it is necessary that no inflammable material should be used.

Where it is desirable to erect a building with more than one floor, or where galleries are required in a machine shop, these are best constructed with a main framework of steel. The stanchions should be composed of rolled steel joists, or of compound sections, as shown in figs. 9 and

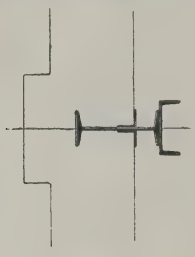

FIG. 6.

FIG. 7.

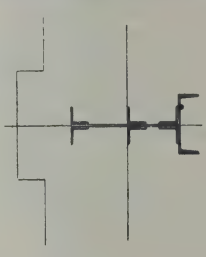

FIG. 8.

Types of Wall Stanchions to carry Cranes.

10, the main floor girders being rolled steel joists or plate girders, as required by the loads coming upon the floor. The depths of the main joists and girders should not be less, if possible, than $\frac{1}{12}$ of the span.

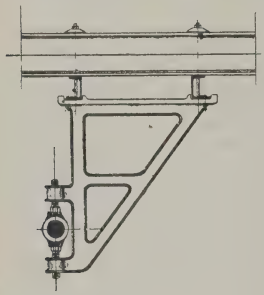

FIG. 9.

Detail Connections for carrying Shafting.

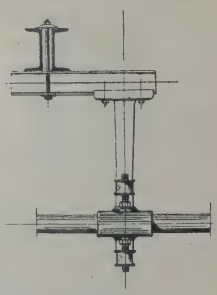

FIG. 10.

The use of a steel frame construction is especially desirable in a building of more than one storey, as the lower floors are dependent for light on the windows, which are placed in the side walls. If steel framing is used, the covering material of brickwork or concrete can be reduced to a minimum, and the window area is correspondingly large.

Floors.

Floors are now generally made of concrete, either with or without a covering of timber.

When the wearing surface is of concrete it should be finished with granite sand and cement, in equal proportions for the thickness of one inch. Concrete is not so suitable as wood for the wearing surface of a floor. It is always impossible to ensure freedom from cracks in concrete over large areas, it is tiring to walk on, is dusty, and liable to damage tools and fragile articles dropped upon it.

If a wood floor is used it is usually laid on a foundation of cement concrete, usually from 4 ins. to 6 ins. in thickness, this being a variable dimension depending on the loads to be put upon the floor, and on the nature of the subsoil.

For floors where the work is of a heavy description the best surface is one of wood blocks 4 ins. deep, which may be formed by sawing off 3-inch deals to lengths. To prevent damp from rising through the concrete the upper surface of the foundation should receive a coat of coal tar pitch about $\frac{1}{4}$ inch thick applied hot, and the blocks should be dipped in the hot coal tar and bedded whilst the pitch is hot, any open joints being afterwards run in with pitch. Where the work is of a lighter character, the most satisfactory wearing surface is grooved and tongued maple planking, nailed either to 4-inch by 3-inch battens laid in the concrete or to planks laid transversely.

The battens should be creosoted, or dipped in 'Jodelite' or 'Sideroleum,' or some similar wood preservative, and the planking laid in hot tar. It is very important that the whole surface of the floor should be thoroughly tarred before the wood blocks or planking are laid, and that any wood blocks or pegs used for levelling purposes should be removed. Where the loads are very light and the foundation good, tar concrete may be substituted for the cement concrete, the upper surface being tarred as before.

The supported floors of a multi-storey building, or of galleries, are usually constructed of concrete where a fire-resisting floor is required, or of timber in other cases. Where a concrete floor is used it may be constructed of reinforced concrete, or preferably of rolled steel joists and concrete, as the more or less concentrated loads from machines and materials coming on the floor can be more easily arranged for.

In this case the floor can be constructed of small steel joists from 4 ins. to 7 ins. deep, according to the span and load, spaced about 2 feet apart, and finished with a flat ceiling. If the concrete is arched or recessed between the joists, hangers can be easily attached by hook bolts to carry countershafting. Another method where the loads are considerable is to use joists of heavier section, and to form an arched floor of concrete between these.

The upper surface of the floor can be finished with wood planking, as previously described. If the floor is constructed of timber, wood joists bedded on the steel main girders can be used, with wood planking laid on top. It is well, if this form of floor is used, to finish the floor with boards from 1 in. to 1¼ in. in thickness, nailed transversely to the planking. Both the planking and the boarding should be thicknessed and laid with grooved and tongued joints.

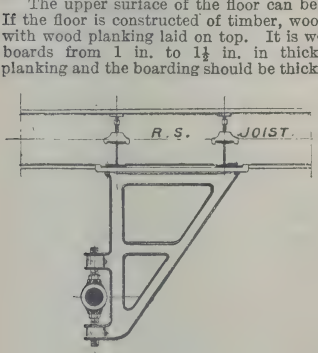

FIG. 11. Detail Connections for carrying Shafting.

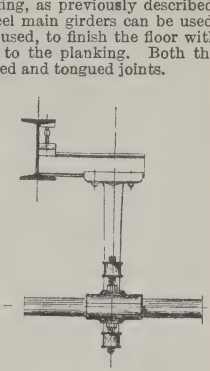

FIG. 12.

Window sashes are best formed of steel, which if properly painted at intervals is as durable as wood, offers less obstruction to the light, especially in windows of large size, and can be obtained at the same or less cost. The heads to windows may be brick arches, but are preferably formed of concrete, reinforced with small rolled joists or tees.

The position of the sanitary conveniences should be arranged so that undue time is not wasted by a long journey from the shop and back. The minimum accommodation is fixed by the Factory Acts, and the Bye-laws of the local authorities. A regulation of the Factory Acts which is strictly enforced by most local authorities, requires the conveniences to be cut off from the main building by a free air space, and this is undoubtedly desirable from a sanitary point of view.

The foreman of a shop should have a desk and office in that shop. The position should be arranged so as to give him a convenient oversight over the whole of the men employed.

The office may consist of a portion of the shop railed off or of a small wood building glazed all round and raised above the general floor level so as to overlook the shop.

Dry grinding machinery is always to be exhausted by a fan.

Smith work is best done in a separate building. Light smiths' fires are supplied with exhausting fans to clear the smoke.

Wood-working shops may be fitted with exhausters to remove all waste, which is best delivered to the boiler house and destroyed.

As no work can be done cheaply without thorough gauging arrangements, the modern method is to use the limit gauge system, for which purpose every works must have a full set of accurate high-class gauges to be used with special care in testing the working gauges, which may be made of cheaper material, and rejected as wear places them out of the limit of accuracy required.

Finished parts should be inspected as made, and finished machines when ready for shipment.

The tool room is an essential department in a modern workshop. In it are kept all tools and gauges required, and every tool given out for use should have a check in its place in the tool room. Fixtures, belts, and other requisites for different tools should have a place on a shop stand, which may be simply a shelf or two of plate iron, supported by pipe framing. No accumulations must ever be allowed on the floors and in corners. Conical pointed buckets provided for dirty waste cannot be left standing about, but must always be in place in their ring stands.

Provision must be made for the prompt removal of all chips, especially if greasy. Where automatic machinery is employed, oil is pumped over the work by a pump in the machine itself. In some shops oil is supplied in pipes, and returns to the pumps through pipes by way of filters. Machines very freely supplied with oil for the tools should be stood on lead-protected floors to prevent oil soakage. Greasy chips can be purified of oil in a centrifugal machine.

In a large works a tool room in each room or on each floor may be required; but no more than actually needful should be provided. Preferably rooms should be as large and as few as possible. The tool room fully carried out includes much more than mere storing and providing tools; its duty is to lay out systems of doing work, and to collaborate with the drawing office in regard to materials and stores. It is in a sense not merely a part of the works: it is also a part of the managerial department.

The drawing office also should be more than a mere room for drawing. It is, or should be, the very centre of management, for from it should emanate design, orders for materials, and the intellectual work of the whole establishment, so that design may be kept in touch with materials, market prices, etc.

Where tools are belt driven, it is usual to employ a countershaft between line shaft and tool, but if the line shaft runs at 250 r.p.m., as a modern shaft may well do, the countershaft may be omitted; there would then be a fast-and-loose pulley on the machines themselves, and no cone pulleys, their place being taken by the all-gear headstock in the lathe.

Heavy lathes may be driven from built-in motors set across the bed, and driving through chains a worm shaft with a right and left worm driving worm wheels on each side of the face plate wheel, and pinions in the worm shafts driving this wheel.

The introduction of high-speed steel, with its great capacity for removal of metal and its large absorption of power, has completely changed conditions. In the lathe the tendency is to abandon the stepped belt cone and employ a single belt pulley, only driven, it may be, directly off the line shaft, speed variations being obtained by gearing. Motors are still frequently belted to a machine, but the tendency is towards making the motor an integral part of the machine it drives. Small tools are more economically group driven from a shaft and a single motor. Whether tools shall be driven in groups or by a single motor to each tool can only definitely be decided by the actual conditions of the case. Where every machine has its own motor the aggregate power of all the motors will be two or three times that of the current generating dynamo.

The application of electrical methods has tended to advance gas and compressed air and mechanical hammers to displace steam hammers; but for larger work the steam hammer is still imperative, being superior to any other hammer. But for the very largest work of forging, the hydraulic press now does the best work, and steam hammers are not made equal to dealing with the largest work now undertaken.

In place of hooks for lifting, shop cranes are sometimes fitted with electro-magnets for lifting plates or such articles as can be thus easily held. By this means time is economised, for there is no use for slings, and the load can be put down by the lift man without help from labourers to detach, simply by the turn of a switch.

For much work that is too heavy for easy movement, the machine tools are carried to the work. In this system the floor is of heavy cast-iron girder plates grooved like the platen of a planing machine. Work is laid upon this floor, and machine tools are bolted to the floor, and operate on the work. This is rendered possible by a system of electric driving, the motors being part of the machine. Machine tools may be attached to the work, and the designer should take this into consideration in his design, since by slight modifications the work may be made so as to facilitate such fixing of the tools.

FLOOR SPACE FOR MACHINE TOOLS.

Size.	Machine.	Greatest No. of Machines per 1,000 sq. ft.
12 ins. to 20 ins.	engine lathes, faced same way	20
12 ins. to 20 ins.	engine lathes, back to back	24
22 ins. to 24 ins.	planers, heads and tails	10
22 ins. to 24 ins.	planers, faced same way	9
28 ins. to 30 ins.	planers, faced same way	5
14 ins.	multi-spindle drills	40
16 ins. to 20 ins.	upright drills	36
26 ins. to 30 ins.	upright drills	12
	Small milling machines	36
	Ordinary milling machines and automatic screw machines	20
	Hand screw machines and plain and universal grinders	15
	Polishing machines	24

The above areas are exclusive of main passage-ways, and if it is decided to run a 6 ft., 8 ft., or 10 ft. passage the entire length of building this area must be added.

Every tool in a workshop should be drawn in outline as regards its leading dimensions, and the drawing pasted on a suitable board together with the overall dimensions of the work it will take, the speeds, feeds, and other information for the drawing office.

The drawing office should be the repository of all information as to stock material; it should really include the stores and purchase department, and work in progress in the shop, and during erection should be visited by the draughtsmen chiefly concerned, so that needless costs and charges in manufacture and erection may be avoided.

Concrete Floors.

To deaden the noise from trucks rumbling over a concrete floor, use a heavy tar paper pasted to the floor by paint. The floor to be protected is first given one coating of grey cement paint. On the following day, when the paint is thoroughly dry, a second coat is applied. At the same time one side of a five-ply tar paper is painted; and when both paper and floor are still wet the paper is carefully laid, wet side down, on the floor and rolled with either a roller or wide-tired truck until all signs of air-pockets beneath the paper disappear. The surface improves with age, and very effectively reduces noise at a low cost.—*Contract Record.*

Oil stains on concrete floors may be removed by using a mixture of 1 lb. of oxalic acid in 3 gallons of water, with enough wheat flour added to make a paste that can be applied with a brush. Allow the application to remain for two days, and then remove it with clean water and a scrubbing brush. A second application may be necessary in stubborn cases.—*Building News.*

To remedy dusty concrete floors, a surface treatment of some kind should be applied to remove the surface skin which does not exceed $\frac{1}{32}$ in., or properly to treat it. One way is to grind the surface by hand or power as a terrazzo floor is polished. Other methods are to apply liquid coatings of various kinds. One of the most satisfactory treatments is with boiled linseed oil thinned with petrol to such a consistency that it will penetrate the pores of the surface. If one coat does not cure the trouble generally two will. A second method is to clean the surface thoroughly and then apply a coat of silicate of soda or water glass, 40 deg. Baumé, diluted one part to six of water, to seal the surface. Then wash off the excess which opens out the pores again and apply a second coat.

See also p. 399.

For making slippery iron floor plates reasonably safe under ordinary shop conditions, mix a small quantity of powdered sal ammoniac thoroughly with a large quantity of fine sand. Sprinkle the mixture over the floor so that all parts are covered, and damp the surface with a watering can and let it lie over a week-end, or even overnight, then sweep the sand up. The rust coating formed by the treatment will be found to last for several weeks, after which the process must be repeated.—*Ironmonger.*

Electric Power Driving.

Where many small machines are placed near together and driven more or less intermittently, one small line shaft and one motor will drive all the little machines, and the motor will be of far less cost and power than the aggregate of motors if applied one to each machine. But for large machines, single motors to each machine are a decided economy.—*C. H. Benjamin.*

The Use of High-Pressure Gas in Works.

A satisfactory arrangement is to have a shop supplied with gas at 200 ins. pressure, to be reduced at the various furnaces, etc., by means of governors or valves, to the predetermined pressure corresponding with the temperature it is desired to maintain in each furnace. Pressures suitable for typical work are as follows:—For melting tin or solder a pressure of 65 ins.; for small furnaces for hardening, etc., the same pressure may be used; for blueing steel, from 65 ins. to 80 ins., the flames playing horizontally under the lime-tray set in a brick frame; for the lead-pot for tempering steel the pressure should be 150 ins.; while for melting metals at from 2000° to 2600°F. it should be 200 ins. Soldering-irons may be heated with gas at 65 ins.; two burners, consuming 6 ft. of gas per hour, and playing direct on to the irons, being sufficient to keep a workman going without delays. For lighting, gas at 65 ins. may be used.

With gas at 2*s.* per 1,000 and coal at 20*s.* per ton there is little to choose between gas and coal firing as regards cost. As regards cleanliness, uniformity, etc., the advantages are, however, in favour of gas, and in many cases with properly-designed furnaces it is greatly superior to coal, not only from the point of view of cost, but from convenience and ease of manipulation. A properly-designed gas-furnace will enable the time of preparation from the cold to be greatly shortened.—*A. W. Onslow.*

WORKSHOP PRACTICE.

Limits and Limit Gauges.

Probably two main reasons have delayed the general use of limit gauges among machinists for some years after they were generally recognised as necessary. First, the cost of making them of the usual solid type was so great that they were practically luxuries, except for repetition work—for that they were absolutely essential. Secondly, inasmuch as there was no recognised standard of limits, it was 'easier' to leave the 'fit' to the judgment of the individual workman.

There are four usual 'fits' in practical mechanics, namely—

The *force* fit, which requires a screw, a hydraulic press, or the use of heat on one piece to get the fits together. The *drive* fit, which can be done by a hammer. The *push* fit, which can be pushed together by hand, and may even be revolved slowly, but would heat and seize if run for any time; and the *running* fit, which will run indefinitely if lubricated, and varies with the class of work. Running fits may be divided into several classes, and are classed in three divisions by the Newall Engineering Co.

The provision of a separate external limit gauge for each and every diameter used—and for each variation in the quality of fit required on such diameter—would entail in most cases an expenditure so heavy as to practically prohibit the installation of a full equipment: yet in modern commercial production efficient means of gauging work are imperative, and, to overcome the necessity for the multiplicity of external limit gauges required, an adjustable type was specially designed and introduced by the Newall Engineering Co. These being adjustable, they are not affected by wear as are all solid gauges.

The gauge has two fixed anvils on one jaw and two movable anvils (adjusting screws) on the other jaw, forming two pairs of measuring faces, the front pair being the 'go' and the back pair the 'not go' points; the adjusting screws are securely locked in position by means of cotters and nuts of special design. Each gauge, by the length of travel of its adjusting screws, covers a range of sizes, and can be easily and quickly set up to such diameter and limits within its range as may be wanted.

There are two methods of setting up or adjusting the measuring points. The first is by means of limit reference bars ground to the 'high' and 'low' limits for the different allowances prescribed in standard tables. The other method is with standard reference bars and 'setting dials'; the adjusting screws of the external limit gauges have taper holes in their inner ends, and the dials are provided with taper shanks which fit into these holes. The 'go' and 'not go' points of the gauge are set to a standard reference bar (or other reliable standard) of the nominal size required: the adjusting screws are then locked and the dial and index inserted at zero. The screw carrying the dial is released and can be adjusted to the desired allowance, either above or below 'standard,' by rotating the screw in the plus or minus direction, as shown by the arrows on the index. This screw is then locked, the dial and index transposed, and the process repeated with the other screw. For English sizes the dials are divided to read by ·00025 in., and for metric sizes by ·01 mm. One pair will serve for all gauges up to 6 ins., or 150 mm.; gauges over these sizes require a larger pair.

Much good work is done by means of standard gauges, and thin paper for giving differences. Such a system cannot be recommended, for it is costly to carry out—costly, that is, in labour. It is a system more suited to the mechanician's laboratory than to the workshop, and though perhaps justifiable in face of the heavy cost of a full set of limit gauges, is not worthy of adoption where adjustable limit gauges can be procured.

Definitions as given by the British Engineering Standards Association:—*Tolerance*—a difference in dimensions prescribed in order to tolerate unavoidable imperfections of workmanship. *Allowance*—a difference in dimensions prescribed in order to allow of various qualities of fit.

(*The Newall Engineering Co., London.*)

Newall Standards.

Class X is suitable for engine and other work where easy fits are wanted.

Class Y is suitable for high speeds and good average machine work.

Class Z is suitable for fine tool work.

Although in the above tables five places of decimals are used, the dimensions actually run in thousandths of an inch and half- and quarter-thousandths.

Limit Arms for Micrometers.

A ready means of converting an ordinary micrometer to a limit gauge having a tolerance of from 0·0001 to 0·022 in. with variations of 0·0001 in. is provided by a pair of arms (fig. 13) manufactured by Messrs. Accles & Pollock, Oldbury, Birmingham. The micrometer having first been set to the low limit required, the pair of arms are cramped compass-friction-tight

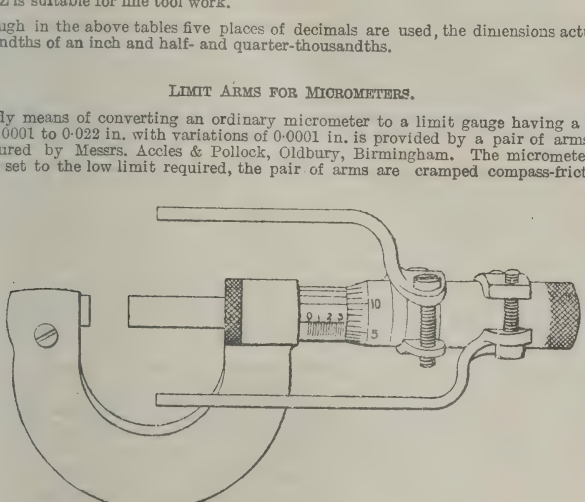

Fig. 13.

on to the micrometer barrel, the short arm just clearing the figures at the bevelled end. The short arm is now adjusted from its cramp end, so that it strikes the back of the frame at the low limit. The screws are then tightened. The long arm is similarly adjusted so that it strikes the front of the frame at the high limit. When the change to new limits is greater than one revolution of the thimble, the screws are slackened, and both arms brought to the top; the procedure is then as before. The ordinary use of the micrometer is not interfered with.

(*Machinery.*)

DEPRECIATION OF PLANT AND MACHINERY.

Depreciation may be divided into, roughly, two classes—(1) deterioration, (2) obsolescence. An annual charge must, therefore, be provided for—(1) deterioration, (2) renewals, (3) obsolescence. Depreciation will be dealt with under these heads, as affecting (1) cost of production, (2) income-tax, (3) fire insurance.

Residual Value.—In dealing with the estimated life of plant or machinery, the residual value of such plant or machinery when its period of usefulness has expired must be taken into account, and with plant of special nature, it may generally be assumed that in proportion to its special character its residual value will be low. Plant of general character, engines, boilers, shaftings, pulleys, etc., carries a high residual value in the event of displacement.

Method.—There are two extreme methods of valuation. (1) To assume an average percentage rate covering the whole plant of, say, 5 to 7½ per cent. on the book value. (2) The individual valuation of each machine, and the writing off of the detailed differences. Both these methods are faulty; in the first the result is hazardous, as the percentage may be assumed on a proportion of general and special plant, which may vary considerably afterwards. In the second place the detail is considerable; it has to be done at a time of pressure, and if left to other hands than those of a principal, the results are generally too favourable. In arriving at a basis, therefore, for the settlement of a depreciation charge, it will be found generally desirable to classify the plant, and by taking the plant and machinery in each department, and abstracting the items of each

under five or six classes, we shall get, in the first place, a departmental separation, and, secondly, a classification under each department of, say—

Motive Power.—Boilers, engines, etc.

Power Transmitters.—Shafting, pulleys, etc.

Process Plant.—Fixed, wearable, loose.

Accessory.—Railway trucks, weighing machines, cranes, travellers, and the like.

By leaving space in each department inventory, we can provide for additions, and by having loose sheets with columns for abstracting, we can economise in rewriting. From these totals a special rate in respect of deterioration, obsolescence, and renewals, based on personal experience, can be applied to each department and subdivision. These particulars will afford a basis for charges in the cost sheets, thus obtaining a departmental depreciation charge. A fixed rate can then be adopted.

Diminishing Value.—Before establishing a percentage rate on these classes of plant, a basis must be settled on which the rates are calculated. For some years the basis of the diminished value obtained by the writing off of the annual depreciation charge has been generally adopted, but latterly there has been a tendency to revert to the basis of original cost. For instance, a rate of 10 per cent. on the original cost will exhaust the value in ten annual instalments; but a rate of about 16½ per cent. would be required to exhaust the value in the ten years if calculated on the diminishing value remaining after the deduction of depreciation in each year.

The argument in favour of basing the calculation on the diminishing value is that the sums written off in the earlier years were greater when the repairs were small, and this tended to equalise matters. Too often, however, the two factors of rate and basis have not been settled together, and consequently the basis of diminishing value has had the effect of leaving a considerable value in the books when the plant has disappeared.

For instance, a 5 per cent. rate generally carries the impression of a twenty years' life, yet taking 100*l.* as the cost, and writing off on the diminishing value, the balance left at the end of the twentieth year is 37*l.* 14*s.* After twenty years' service the residual value of the plant would be, roughly, one-third of the first cost, a figure far too high, and it may be seen that there is room here for considerable improvement. Besides this, adopting the basis of original cost, the position is much clearer for any revision of the rate at any subsequent period.

Depreciation Rates.—Dealing with these subdivisions of the plant in order, we have :—

Motive Power, Boilers, Engines, etc.—Some authorities place the depreciation on engines as high as 12½ per cent., and boilers at 10 to 15 per cent. Much depends on stress of working and the water. Mathieson places the life of a boiler at fifteen years, with renewal of the furnace at the end of ten years, and recommends a rate of 7½ per cent. per annum on the diminishing value on this class, no provision being made for obsolescence. This is, however, an extreme view.

Power Transmitters.—Shafting, pulleys, and plant under this head have, as a rule, a high residual value, even if displaced, and probably a rate of 5 per cent. will be found sufficient provision. Belting should be classified as loose tools. In this class a rate of 5 per cent. would be recommended, divided into 3 per cent. for deterioration and a renewal rate of 2 per cent. No provision is made for obsolescence.

Process Plant, Fixed.—Under this head would be placed all heavy process plant, the renewal portions of which are classified under their separate heading. The deterioration would then be met by a rate of 2½ per cent., the renewal rate at 2½ per cent. An obsolescence rate depended on the nature of the processes.

Process Plant (Wearable).—The exteriors of this plant under our classification have already been dealt with, and it is necessary therefore to provide a heavy renewal rate. By the dissection of this plant under the shop totals the separation of the different process plants has been secured, and it is easy to apply to each shop total a distinctive rate for renewals applicable to its character and requirements. This will be readily based on experience.

Process Plant (Loose).—In the case of loose tools, the yearly valuation gives the most reliable results. In some cases there is an annual increase in this class, but this should verify itself. It is to be remembered that at a going-concern valuation this cannot, in the nature of the plant, work out at more than half the original cost value.

Accessory Plant.—In this case there is a high residual value due to general utility, and consequently a rate for deterioration of 2½ per cent. and a renewal rate of 2½ per cent. should suffice.

Horses, Carts, Harness, etc.—The risks and depreciation on this class are too great to include in any average rate. The treatment accorded to loose tools of a revaluation annually gives probably the best results.

Depreciation and Income-Tax.—The problems of income-tax and fire insurance are mainly connected with the rate of depreciation. The rate of depreciation allowed under the Income-tax Acts differs considerably in different localities. For instance, the rate of depreciation allowed to engineers in Leicester is 7½ per cent. on the full value, while in Cardiff the rate is only 5 per

cent. on the diminished value. Hosiery machinery in Leicester obtains 7½ per cent. as against 5 per cent. on lace machinery in Nottingham. Dyers' machinery in Leicester can get 10½ per cent., if justified on enquiry. Generally speaking, a distinction is made between motive power and process plant, and the general practice assumes 5 per cent. on motive power and 7½ per cent. to 10 per cent. on process plant; these allowances are in respect to the two headings of deterioration and renewals. There appears to be no annual allowance for obsolescence at present, but where claims are made an allowance is made from the assessment for plant which is scrapped to the full amount at which the same stood in the books at the previous stock-taking. With regard to horses, no allowance is made, but the full costs of replacement are to be charged as they occur.

Fixtures.—On these no allowance for depreciation is made, unless they are included under the head of plant. Any replacements are allowed in full against the year's working.

The Inland Revenue authorities have now reverted in a number of cases to the basis of original cost, and where, say, 5 per cent. is allowed on original cost, there is an alternative rate of 7½ per cent. allowed on diminishing value.

Renewals.—The practice adopted by the income-tax authorities provides for the charging up of renewals to capital account where depreciation is allowed, and they usually decline to allow both renewals and depreciation as a charge against the year's profits. The result is to treat renewals as capital expenditure, which in turn are subject to depreciation at the rate agreed on. Taking Mathieson's example of the life of a boiler at fifteen years, at the end of ten years, when furnaces have to be renewed, it will be seen that by charging renewals to capital only 25 per cent. of the cost of the renewal before the expiration of the life period can be provided. Therefore, to charge renewals to capital, there must be included in the calculation of the rate of depreciation the provision for renewals along with deterioration. The modern tendency is to separate renewals from depreciation and to provide a fixed sum annually against renewals and repairs, charging the yearly outlay under both these heads against the sum thus accumulated, and leaving depreciation to include deterioration and obsolescence only.

Fire Insurance and Depreciation.—The writing down of machinery and plant by an increased rate of depreciation, the value in the case of a fire would be affected in the claim for replacement. It is usual in some offices to append a declaration on the face of the policy that the depreciation written off in the books shall not be taken for the purpose of assessing a fire loss. Usually the assured is covered for the value of the plant at the time of the fire, and that the original cost of the plant, less depreciation, is not necessarily the basis of the claim. There appears to be no scale of depreciation in force for different kinds of plant recognised by the insurance companies, but these losses are generally settled as between the assessors and surveyors acting for both parties, or, failing their agreement, by arbitration: no special rates are applicable, but each case is settled on its merits. The principal factor appears to be the possession of definite and specific information on the value and cost of the plant, and the rate of depreciation does not in any way govern the claim in case of fire.

It is a general provision in fire insurances and policies that the company may elect to replace the plant; instances of this have rarely occurred, if ever, and probably it was never intended as other than a protection to the company.

There exists a considerable controversy as to the proper authority to fix the rate of depreciation, but it is now generally accepted that for depreciation the engineer, and for financial consideration the auditors, take first place.—*Herbert T. Howell.*

The following rates of depreciation have been recently authorised by the Government of Australia in connection with the Federal income-tax on industrial establishments:—Boilers, 5 per cent.; boring machinery, 10 per cent.; cables, aerial, 7·5 per cent.; cables, underground, 2·5 per cent.; condensers, 5 per cent.; cranes, 5 per cent.; elevators, electric, 7·5 per cent.; elevators, hydraulic, 10 per cent.; engines, steam, 5 per cent.; foundry cupolas, 15 per cent.; furniture, 5 per cent.; generators, 5 per cent.; machine tools, 5 per cent.; machinery used in ordinary manufacturing, 5 per cent.; meters, switchboard, 7·5 per cent.; motor trucks, 10 per cent.; patterns, 15 per cent.; pumps, 5 per cent.; galvanised iron tanks for rain water, 5 per cent.; galvanised iron tanks for other water, 10 per cent. The figures are based on the diminishing value of the assets and not on their original cost.

Memorandum by the Board of Inland Revenue on the subject of Income Tax Allowances for Depreciation and Obsolescence of Plant and Machinery, etc.

Replacement of Obsolete Machinery or Plant.

In addition to the allowance for wear and tear of plant and machinery there has been in operation since 1897 an allowance for obsolescence, and this allowance has been made statutory by Section 24 of the Finance Act, 1918.

The necessity for this allowance arises from the fact that machinery has frequently to be replaced before it is worn out, owing to its having become obsolete and incapable of competing with more up-to-date machinery. Accordingly, where new machinery is introduced in place of machinery not wholly worn out, an allowance is made, as a deduction from the profits of the year,

of so much of the cost of replacement as is equivalent to the written down value of the machinery replaced less any sum realised by the sale of it, the balance of the cost of the new machinery being an addition to the capital of the business.

For example, from the value of a machine which originally cost 1,000*l.*, wear and tear allowances have been made year by year until they have aggregated 600*l.*, so that the written down value of the machine stands at 400*l.* The trader now considers that the machine is obsolete, scraps it and replaces it by an up-to-date machine which costs 1,400*l.* He sells the old one for 50*l.* He is entitled to charge as a trade expense incurred in the year in which the replacement is made the sum of 350*l.*, that is—

	£	£
Original cost of the machine replaced		1,000
Less (*a*) aggregate amount of wear and tear allowances already made in respect of the machine	600	
(*b*) sum realised by its sale	50	
		650
Amount treated as trade expense in year of replacement		350

Assuming the total written down value of the trader's plant and machinery before the sale of the obsolete machine to be 10,000*l.*, future wear and tear allowances will be made upon a value of 11,000*l.*, thus :—

	£
Written down value of total plant, etc.	10,000
Deduct written down value of the obsolete machine	400
	9,600
Add cost of new machine	1,400
	11,000

The obsolescence allowance is not made in quite the same way as the wear and tear allowance, for the latter is by Statute an allowance from the assessment *after* the three years' average is struck. Thus the wear and tear allowance applicable to the year 1918–19 would be given as a deduction from the gross assessment for 1918–19 as follows :—

	£
Trading profits (beofre allowing wear and tear)—	
1915—Loss	5,000
1916—Profit	10,000
1917—Profit	13,000
	3)18,000
Gross assessment 1918–19	6,000
(If the total wear and tear allowance due for the year 1918–19 were 6,500*l.* a sum of 6,000*l.* would be allowed against the 1918–19 assessment, and the balance of 500*l.* carried forward for deduction in future years.)	
Wear and tear allowance	6,000
Net amount on which tax is payable for 1918–19	nil

An allowance for obsolescence in 1918 of say 10,000*l.* would, however, be a deduction from the commercial profits of 1918, turning them from a profit of say 9,800*l.* to a loss of 200*l.* The first assessment to be affected would be that of 1919–20, as follows :—

	£
Profits 1916	10,000
1917	13,000
1918—Loss	200
	3)22,800
Gross assessment 1919–20	7,600
Less—	
Allowance for wear and tear, say, 6,800*l.*, for 1919–20, plus the unexhausted balance carried forward from 1918–19, 500*l.* =	7,300
Net amount on which tax is payable for 1919–20	£300

The business year 1918 would also come into the average for the tax years 1920–21 and 1921–22, by which time the allowance would have had its full effect.

Cost of Renewals as an Alternative Method.

As an alternative to the allowance for wear and tear and obsolescence of plant and machinery the cost of renewing plant and machinery may be claimed as a deduction in the computation of Income Tax liability under Schedule D. When this course is preferred by the taxpayer the amount to be allowed is the actual cost of the new plant and machinery (excluding any part of such cost which is attributable to additions or improvements, i.e. to an increase in capital) after deducting the scrap value or realised price of the plant and machinery replaced.

Example (a).—A machine which originally cost 1,000*l.* is worn out and replaced by a machine of similar power or size or capacity which now costs 1,500*l.* The whole of this expense of 1,500*l.* is allowable from the profits of the year in which it is incurred.

Example (b).—A machine which originally cost 1,000*l.* is worn out and replaced by one of greater power or size or capacity costing 2,500*l.* The amount to be allowed as an expense is in this case not the full 2,500*l.*, but only the cost of replacing the old machine by one of similar power or capacity, say 1,500*l.*

Although this method of allowance is alternative to the wear and tear allowance for the same class of plant, the two principles may run concurrently for different classes of assets in the same business. For example, the wear and tear allowance may apply to fixed machinery, while the renewal method is used for loose plant.

Estimating Cost of Steel Bars.

Locate on axis OA (fig. 14) the position which represents the price in shillings per cwt. at which the particular steel can be bought. From that point travel to the right, horizontally, until the diagonal which represents the diameter of bar required is reached. From that point pass vertically down to axis OB and read off the price per foot for bar of that diameter in the material required.

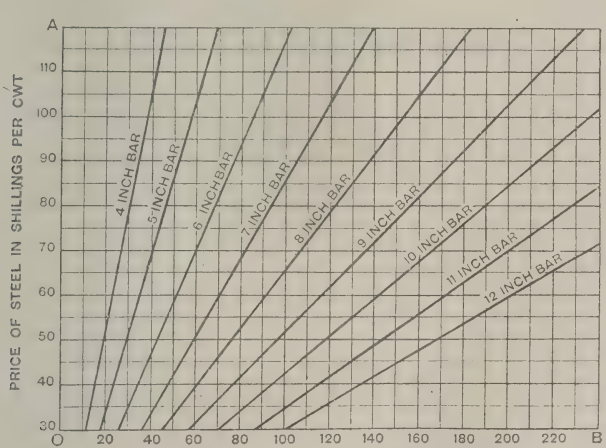

Fig. 14.

The chart covers steels from common mild steel to high grade nickel-chrome steels, and it can be used for determining the value of forgings if the price of plain forgings per cwt. is known.

(*Howard Ensaw, 'Machinery.'*)

SECTION XVI

FLOUR MILLING—COTTON MILLS—OIL MILLS—CANE SUGAR MILLS AND MACHINERY

SECTION XVI

FLOUR MILLING — COTTON MILLS — OIL MILLS — CANE-SUGAR MILLS AND MACHINERY.

FLOUR MILLING.

(Contributed by E. R. & F. Turner, Ltd., Engineers, Ipswich.)

Fifty years ago the reducing of wheat to flour was done almost entirely by means of stones; now it is done by chilled iron rolls, except in a few countries where stones are still retained.

Stones are still used in England and elsewhere for making 'stone' flour, whole meal, farmers' grist, etc. They are usually from 36 to 48 ins. in diameter, top stone the runner, driven by gearing from a horizontal layshaft; speed about 150 revs. per minute; horse-power required from 8 to 12 b.h.p., but largely dependent on the condition of the grain and the sharpness of the dress in the stones.

ROLLER SYSTEM.

The very white, high-class flour of the present day is obtained by means of a very elaborate system. Every mill of any size is fitted with:—

1. Intake plant. 2. Wheat-cleaning plant. 3. Milling plant.

The intake plant for getting the wheat from trucks or barges into the mill may be either pneumatic (suction) or elevator, and is arranged so that the wheat may be deposited into any one of the storage bins or silos provided for the purpose.

The cleaning plant consists of scourers, aspirators, brush machines, etc., and also includes a plant for washing and drying such wheats as require this treatment.

The milling plant consists of roller mills, purifiers, and dressing machines connected by spouts, elevators, and conveyors. The actual roll contact surface is usually about 100 ins. per sack of 280 lbs. of flour per hour, which is divided up into approximately 40 ins. on the break rolls and 60 on the reductions. The break rolls are fluted from about 12 to 26 per inch, for opening the wheat berry, releasing the kernel and cleaning the bran, which is separated by means of sieves; the reduction rolls are smooth or very finely fluted or scratched, and reduce the kernel into fine flour, which passes into sifting machines and is dressed through fine silk. Sifting machines may be either of the reel type with internal beaters, commonly called 'centrifugals,' or the flat sieve, called 'plansifters,' both types being covered with silk containing from 100 to 150 threads per lineal inch for dressing out the finest flours, or coarser if required.

The semolina and middlings released by the break rolls are passed through purifiers in which strong currents of air pass through them, eliminating fine branny particles and other impurities before they are passed on to the reduction rolls.

Exhaust fans are connected to all machines for drawing away the hot air which is generated by the rolls and other frictional surfaces.

One sack of flour (280 lbs.) is made from 400 lbs. of wheat.

Angles of spouts for wheat should be not less than 25 degrees, and for flour and bran not less than 55 degrees.

Speed of elevators for wheat 300 to 350 feet per minute.
" " flour 180 feet per minute.
" " other mill stock 220 feet per minute.
Speed of spiral conveyors 150 feet per minute.
" band conveyors for wheat 9 feet per second.
" " " light stock 3 feet per second.
" break rolls 900 feet per minute.
" reduction rolls 630 feet per minute.

Power required about 10 to 12 b.h.p. per sack of flour per hour.

COTTON MILLS.

(BLACKBURN DISTRICT. YATES & THOM, ENGINEERS.)

For 90,000 mule spindles and preparation.
Main building, 281 feet by 130 feet; 4 floors; 3 spinning rooms; 1 card room.
74 self-acting mules. Indicated horse power, 1,380. Boiler-pressure, 160 lbs.
Engines.—Triple-expansion double-tandem condensing; one high-pressure cylinder, one intermediate cylinder, two low-pressure cylinders :—

Diameter of high-pressure cylinder, 21 inches; ratio, 1·0; stroke, 5 feet 6 inches.
Diameter of intermediate-pressure cylinder, 34½ inches; ratio, 2·7; speed, 60 per minute.
Diameter of each low-pressure cylinder, 39 inches; ratio, 6·9; piston speed, 660 feet per minute.

Rope pulley 30 feet diameter, grooved for 32 ropes 1⅝ inch diameter.
Velocity of ropes, 5,654 feet per minute.
Boilers.—Steel. 4 Lancashire type (one being spare); length, 30 feet; diameter, 8 feet. Furnaces, diameter 40 inches; working pressure, 160 lbs.
Economiser.—Green's type, from 278 to 384 pipes.
Mill Shafting.—Card shaft, 185 revolutions; 3⅜ inches to 2½ inches diameter.
9 drawing frames, 9 slubbing frames, 16 intermediate frames, and 44 roving frames of 176 spindles.
Roving shaft, 270 revolutions, 3½ inches to 2½ inches diameter.
Drawing, intermediate, and slubbing shaft, 225 revolutions, 3⅜ inches to 2½ inches diameter; drives also 27 cards.
Spinning-room shafts, 4¼ inches to 2¾ inches diameter.

For 71,000 ring spindles and preparation.
Boilers.—Four Lancashire, 30 feet by 8 feet, 160 lbs. per square inch, with Green's economiser of 384 pipes.
Engine.—Horizontal cross compound, 1,700 i.h.p. at 66 r.p.m.
Cylinders, 30 inches and 60 inches diameter by 5 feet stroke.
Jet condenser 50 cubic feet capacity. Two air pumps, each 31 inches diameter by 17-inch stroke at 66 r.p.m.
Flywheel, 24 feet diameter, 57 tons. 43 ropes 1⅜ inch diameter.
Rope-speed, 4,970 feet per minute; i.h.p. per rope, 39·5.
Piston speed, 660 feet per minute; air-pump speed, 187 feet per minute.
Cylinder ratio, nominal 4 to 1; mean p, 30 lbs. per square inch.
Machinery.—Includes 15 opening and scutching machines, 132 cards, 18 drawing frames, 11 slubbing frames, 16 winding frames, 22 intermediate frames, 48 roving frames, 164 ring frames of 432 spindles each, 22 beaming machines, 6 warping mills, 100 reels, and 4 bundling presses.

The following are plants completed at Royton, Rochdale, Leigh, and Atherton, by Messrs. Yates & Thom, just before the war :—

ROYTON.

For 117,584 mule spindles, 10's to 24's counts.
Horizontal cross compound engine cylinders, 28 inches and 58 inches diameter, 5 feet stroke, 1,600 i.h.p; 65 revolutions per minute.
Four boilers, 30 feet long, 8 feet 6 inches diameter, 180 lbs. pressure.
Economiser, with 480 pipes.
Fly rope pulley, 24 feet diameter; 40 1⅝-inch ropes.

For 132,000 mule spindles, 10's to 42's counts.
Horizontal cross compound engine cylinders, 28 inches and 58 inches diameter, 5 feet stroke, 1,600 i.h.p. ; 65 revolutions per minute.
Four boilers, 30 feet long, 8 feet 6 inches diameter, 180 lbs. pressure.
Superheaters.
Fly rope pulley, 24 feet diameter ; 40 1⅝-inch ropes.

ROCHDALE.

For 41,000 mule and ring spindles, 3's to 12's counts.
Horizontal cross compound engine cylinders, 19 inches and 40 inches diameter, 4 feet stroke, 600 i.h.p. ; 70 revolutions per minute.
Two boilers, 32 feet long, 8 feet 6 inches diameter, 180 lbs. pressure.
Economiser, with 192 pipes.
Fly rope pulley, 22 feet diameter ; 21 1⅝-inch ropes.

LEIGH.

For 94,560 mule spindles, 40's to 80's counts.
Horizontal cross compound engine cylinders, 23 inches and 50 inches diameter, 5 feet stroke, 1,200 i.h.p. ; 65 revolutions per minute.
Three boilers, 30 feet long, 8 feet 6 inches diameter, 180 lbs. pressure.
Economiser, with 288 pipes.
Fly rope pulley, 24 feet diameter ; 33 1⅝-inch ropes.

For 85,000 mule spindles, 40's to 90's counts.
Horizontal cross compound engine cylinders, 23 inches to 50 inches diameter, 5 feet stroke, 1,200 i.h.p. ; 65 revolutions per minute.
Three boilers, 30 feet long, 9 feet diameter, 180 lbs. pressure.
Economiser, with 288 pipes.
Superheaters.
Fly rope pulley, 24 feet diameter ; 33 1⅝-inch ropes.

ATHERTON.

For 100,000 mule spindles, 60's to 90's counts.
Horizontal cross compound engine cylinders, 28 inches and 56 inches diameter, 5 feet stroke, 1,500 i.h.p. ; 66 revolutions per minute.
Four boilers, 30 feet long, 8 feet diameter ; 165 lbs. pressure
Economiser, 384 pipes.
Fly rope pulley, 24 feet diameter ; 37 1¾-inch ropes.

(*STOCKPORT DISTRICT. J. & E. WOOD, ENGINEERS, BOLTON.*)

For 53,000 ring spindles and preparation.
Main building, 249 feet by 95 feet ; 5 floors and basement.
140 ring spinning frames of 376 to 396 spindles each, spinning 16's to 40's yarn.
Indicated horse-power, 1,500. Boiler-pressure, 165 lbs.
Engines.—Triple-expansion condensing double-tandem type : 1 high-pressure cylinder, 1 intermediate-pressure cylinder, 2 low-pressure cylinders :—

Diameter of high-pressure cylinder, 23 inches ; ratio, 1·00 ; stroke, 5 feet.
Diameter of intermediate-pressure cylinder, 37 inches ; ratio, 2·60 ; speed, 60 revolutions.
Diameter of low-pressure cylinder, 42 inches ; ratio, 6·66 ; piston speed, 600 feet.

Rope pulley 30 feet diameter, grooved for 52 ropes 1⅜ inch diameter.
Rope velocity, 5,655 feet per minute.
Boilers.—Steel. 4 Lancashire type, 30 feet by 8 feet (one being spare). Pressure, 165 lbs. Furnaces, 39 inches diameter.
Economiser.—Green's type, 448 pipes in 7 groups of 64 pipes each. Feed temperature, 75° F. Delivery to boilers, 320° F.
Chimney.—210 feet high, 8 feet diameter inside at top.
Machinery.—96 cards (flat revolving type), 50-inch cylinder by 45 inches wide ; 4 drawing frames, each 3 heads, 4 deliveries ; 12 drawing frames, each 2 heads, 8 deliveries ; 12 slubbing frames, 104 spindles each ; 20 intermediate frames, 140 spindles each ; 52 roving frames, 180 spindles each ; 140 spinning frames, 376 to 396 spindles each.

(HEYWOOD DISTRICT.)

Engines.—The triple expansion condensing engines of the Mutual Spinning Company of Heywood were tested by Mr. J. F. L. Crosland with the following results :—

High-pressure cylinder, 21 inches diameter ; ratio, 1·00 ; stroke, 6 feet.

Intermediate-pressure cylinder, 33 inches diameter ; ratio, 2·50 ; speed, 53 revolutions.

Low-pressure cylinders, 35 inches diameter ; ratio, 5·61 ; piston speed, 636 feet per minute.

Total indicated horse-power, 1,090. Boiler-pressure, 156 lbs.

Cylinder vacuum, 11·2 lbs. ; condenser vacuum, 12·2 lbs. ; injection, 101° ; hot-well, 133° ; steam (2·5 per cent. wet) per horse-power hour, 12·51 lbs. ; dry, 12·2 lbs.

Dry coal per I.H.P. hour, 1·37 lb.

Economiser.—288 pipes ; mechanical stokers.

Boilers.—Two Lancashire boilers, 30 feet by 8 feet ; 66·5 square feet grate surface. Feed to economiser, 130° ; to boilers, 304°. Heating surface : boilers, 2,016 feet ; economiser, 2,880 feet.

Coal : Bituminous slack, 5·6 per cent. ash ; evaporating from and at 212°, 10·36 lbs., of which 16½ per cent. due to feed-heater. Coal per square foot of grate, 24·16 lbs. I.H.P. of engines, shafting and belts on loose pulleys, 242.

Egyptian Yarn (Fine).

For spinning fine yarns an indicated horse-power of 1,900 is found to drive 132,000 mule spindles and other preparation machinery at the Irwell Bank Mill, near Bolton.

Weaving Shed.

(BLACKBURN DISTRICT. YATES & THOM, ENGINEERS.)

172 feet 6 inches by 136 feet, to contain 512 looms.

Boiler.—One, 30 feet by 8 feet, 100 lbs. steam pressure.

Economiser.—96 pipes.

Engines.—Compound side-by-side type.
High-pressure cylinder, 16 inches diameter
Low " " 28 " " } Stroke, 4 feet ; revolutions, 55.
Fly rope pulley, 20 feet diameter ; 7 grooves for 1⅝ rope.

The following are plants completed at Great Harwood and Leigh, by Messrs. Yates & Thom, just before the war.

Great Harwood.

Three weaving sheds, each containing between 800 and 1,000 looms, 36 inches to 58 inches wide.

Horizontal cross compound engine cylinders, 17 inches and 34 inches diameter ; 3 feet 6 inches stroke, 450 i.h.p. ; 75 revolutions per minute.

Economiser, 128 pipes.

One boiler, 32 feet long ; 8 feet 6 inches diameter ; 160 lbs. pressure.

Fly rope pulley, 14 feet diameter, for 14 1¼-inch ropes.

Leigh.

Two weaving sheds, each containing 900 looms, 32 inches to 57 inches wide.

Horizontal cross compound engine cylinders, 16 inches and 32 inches diameter ; 3 feet 6 inches stroke ; 400 i.h.p. ; 80 revolutions per minute.

Boiler, 30 feet long ; 8 feet 6 inches diameter ; 180 lbs. pressure.

Economiser, 96 pipes.

Fly rope pulley 15 feet ; 11 1¼-inch ropes.

Spinning and Weaving Mill.

Bury.

26,000 mule spindles, 32,000 ring spindles, 10's to 44's counts.
750 looms.
Horizontal cross compound engine cylinders, 33 inches and 66 inches diameter ; 5 feet stroke; 2,000 i.h.p. ; 65 revolutions per minute.
Five boilers, 30 feet long ; 8 feet diameter ; 175 lbs. pressure.
Economiser, 480 pipes.
Fly rope pulley, 24 feet diameter for 46 $1\frac{3}{4}$-inch ropes.
Superheaters.

Mule Spinning Mill.

(OLDHAM DISTRICT. POLLIT & WIGZELL, ENGINEERS, SOWERBY BRIDGE.)

Mill 5 floors and cellar, 355 feet long, 129 feet wide inside; 107,000 spindles, counts 8's to 40's one-third weft, two-thirds twist ; 1,650 indicated horse-power.

Engines.—Cross compound horizontal :—
High-pressure cylinder, 26 inches diameter
Low " " 52 " " } each 5 feet stroke, 75 revolutions per minute.
Flywheel 22 feet diameter, turned for 36 ropes $1\frac{5}{8}$ diameter. Weight of wheel-rim 36 tons.
Coal used for all purposes, 70 tons in summer, 84 tons in winter, per week.

Boilers.—6 Lancashire, 5 working, 1 cleaning ; 30 feet long, 8 feet diameter ; working pressure, 160 lbs. superheated.

Economiser.—Green's, 480 pipes.

Chimney.—7 feet diameter, 180 feet high ; main flue 8 feet high, 4 feet wide.

Mill Shafting.—Card-room shafts, 220 revolutions with 18-inch pulleys for drawing, roving, and intermediate frames ; 170 revolutions for cards with 16-inch pulleys. Mule-room shafts, 300 revolutions with 30-inch pulleys.

In the Yorkshire district it is not unusual to carry on cotton spinning in a shed of one floor as in India.

Ring Spinning Mill.

(POLLIT & WIGZELL, ENGINEERS, SOWERBY BRIDGE.)

One-floor shed, 203 feet wide, 346 feet 6 inches long ; in bays, lengthway, 10 feet 6 inches pitch ; 36,000 spindles, counts 0's to 32's ; average indicated horse-power 995.

Engine.—Tandem horizontal compound :—
High-pressure cylinder, 21 inches diameter
Low " " 42 " " } each 5 feet stroke, 75 revolutions per minute.
Flywheel 20 feet diameter, grooved for 26 ropes $1\frac{5}{8}$ diameter. Weight of rim, 30 tons.
Coal used for all purposes, 40 tons in summer, 58 tons in winter, per week.

Boilers.—3 Lancashire, 30 feet long, 8 feet diameter ; working pressure, 160 lbs., superheated.

Economiser.—Green's, 272 pipes.

Chimney.—5 feet 6 inches diameter, 150 feet high ; main flue, 7 feet 6 inches high, 3 feet 3 inches wide.

Mill Shafting.—Card shaft, 175 revolutions with 17-inch pulleys ; drawing, roving, and intermediate frame shafts, 254 revs. with 27-inch pulleys ; spinning shaft, 254 revs. with 42-inch pulleys. The last seven bays of the shed are utilised for winding, reeling, and warping.

Boilers.

A Lancashire boiler to work at 160 lbs. pressure for a modern cotton-mill will usually be 30 feet long, 8 feet 6 ins. diameter, shell and end plates of $\frac{13}{16}$-inch steel with double butt strips, which in good work may be of equal breadth and treble riveted ; or the outer strap may be narrower than the inner strap and having only the double riveting. Furnaces and flues $\frac{9}{16}$ inch plate. The whole of the steel to be of 26 to 30 tons tensile strength, and to elongate not less than 20 per cent. in a length of 10 inches. For furnaces, steel with a tensile strength up to 32 tons is sometimes allowed.

Economisers.

THE 'GREEN' ECONOMISER.

(See page 1525.)

Main Driving Ropes.

The main driving of cotton-mills is usually by cotton ropes of $1\frac{3}{8}$ inch to $1\frac{5}{8}$ inch diameter, the present tendency being towards the smaller diameter. The following tables are deduced from the weights of pure cotton ropes made by a Lancashire firm :—

Diameter of Rope in inches	$\frac{3}{4}$	$\frac{7}{8}$	1	$1\frac{1}{8}$	$1\frac{1}{4}$	$1\frac{3}{8}$	$1\frac{1}{2}$	$1\frac{5}{8}$	$1\frac{3}{4}$	$1\frac{7}{8}$	2
Weight per foot in pounds	·18	·25	·33	·40	·50	·60	·72	·84	·98	1·125	1·3
Diameter of smallest Pulley advisable	22″	25″	30″	34″	37″	42″	45″	48′	52″	57″	66″
Total stress in Rope in pounds	110	150	195	246	300	360	430	500	600	675	780
I.H.P. at 5,000 feet velocity	9	12	16	20	25	30	36	42	49	56	64

There is no practical difference in the power of ropes between 3,600 feet and 5,600 feet velocity. In Yorkshire, leather ropes $1\frac{1}{2}$ inch square are used, and will drive 80 i.h.p. per rope.

Cotton Yarn Measurement.

Cotton yarn is measured by the hank of 840 yards of single thread, and is said to be of 40's or 60's counts, when 40 hanks or 60 hanks weigh 1 lb. A lea is one-seventh of a hank or 120 yards. A wrap reel is 54 ins. circumference, so that 80 revolutions wind one lea and the skein thus wound is what is tested for strength. The softness of yarn varies with the number of turns per inch put into it. For equal quality in different counts the turns must vary as the square root of the counts. Thus turns per inch $= c\sqrt{\text{counts}}$.

For Indian and American cotton, $c = 3{\cdot}75$ for mule twist ; $3{\cdot}25$ for mule weft ; $4{\cdot}00$ for ring twist.

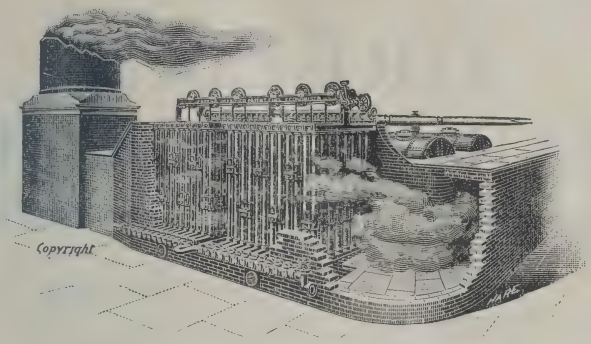
For Egyptian cotton the above values of c become $3{\cdot}606$, $3{\cdot}183$, and $3{\cdot}606$ respectively. Thus 50's American ring twist requires full 28 twists per inch.

List of Machinery in a Lancashire Mill, showing Average 30's Twist on Mules or Ring-frames, with approximate production at each process, speeds, etc.

77,000 Mule spindles for 28's to 32's (average 30's) twist spun counts at 31 hanks per spindle calculated to produce 79,566 lbs. of yarn per week of $55\frac{1}{2}$ hours from American cotton, $4\frac{1}{2}$ hanks single roving, or,

52,800 Ring spindles for 28's to 32's (average 30's) twist spun counts, at 45 hanks per spindle, calculated to produce 79,200 lbs. yarn per week of $55\frac{1}{2}$ hours from American cotton, $4\frac{1}{2}$ hanks single roving.

3 Hopper bale breakers, 36 ins. wide.



3 Automatic hopper feeders, 36 ins. wide, with filling apparatus.

3 Single Crighton cylinder parts, with valves and pipes to the exhaust opener, and lap machine.

3 Exhaust openers and lap machine, 48 ins. wide, for 46-in. laps, with lattice feeder, 4 ft. centres, and dust trunks.

7 Single-finisher scutchers and lap machines, 46 ins. wide, for 45-in. laps, feeder for 4 laps Lap 14 ozs. per yard.

1 Roving waste-opener and feeding-machine.

GREEN'S ECONOMISER

Saves 15-20% of Coal

Ensures a ready supply of Feed Water at from 225°-300° F.

Reduces expansion and contraction strains on boilers, and increases the steaming capacity.

Repays its initial cost in a little over a year.

Is applicable to every type of Steam Boiler.

Write for illustrat descriptive booklet 'AC.'

E. GREEN & SON, LTD.

WAKEFIELD.

GREEN'S ECONOMISER

in conjunction with Steam Boilers

Utilises High Temperature Gases, and saves 15-20 % of the coal usually consumed.

Ensures a large reserve of water at a high temperature to meet sudden demands.

Increases the steaming capacity of boilers.

Reduces expansion and contraction strains.

Is used at Electric Light and Power Stations all over the world.

Increases profits by decreasing the coal account.

Repays initial cost in a little over a year.

Write for fully illustrated and descriptive Catalogue 'AC.'

WAKEFIELD.

Details.	Hanks Roving.	Speed.	Prod. Lbs.	Hanks per Week.
			Each.	
108 Single cards, 45″ on wire, 50″ cyl., 106 s.s. flats, $1\frac{3}{8}$″ wide	0·15	Cyl. 170 r.p.m.	774	116
27 Drawing-frames, 2 heads of 4 deliveries = 27 finishing deliveries	0·13	350 r.p.m. of $1\frac{1}{2}$″ front roller	1150	149
9 Slubbing-frames, 96 spindles each 10″ × $5\frac{1}{2}$″ bobbins × 19″ staff	0·675	600 r.p.m. of spindle	94·8	59·2
17 Intermediate-frames, 140 spindles each 10″ × $4\frac{3}{4}$″ bobbins × $26\frac{3}{8}$″ staff	1·60	750 r.p.m. of spindle	34·1	54·5
42 Roving-frames, 180 spindles each 8″ × $3\frac{5}{8}$″ bobbins × $20\frac{1}{2}$″ staff	4·25	1,100 r.p.m. of spindle	10·6	45·1
74 S.A. mules, 1,100 spindles each 54″ stretch	30's, etc.	10,000 r.p.m.	1·03	31
120 Ring-frames, 440 spindles each $2\frac{1}{2}$″ distance, $1\frac{5}{8}$″ rings, $6\frac{1}{2}$″ lift	30's	9,000 r.p.m of spindle	1.5	45

The above includes for a loss of 1 per cent. at each process, from the card-sliver to the spindle point.

In a modern mill the handling of cotton is reduced to a minimum. The bales of raw cotton are opened and slabs of the fibre flung into the bale-breaker, which delivers either to a mixing-bin or direct to a hopper-feeder, wherein the fibre is automatically regulated to weigh a given weight per yard. Thence it passes forward and is made into laps or rolls. These are removed by hand to the finisher scutcher whence the laps are run by a vertical tramway to the carding engines by hand. The cans of sliver made by the cards, and by the drawing frames and the bobbins, filled at all subsequent operations, must be moved and removed by hand.

The most modern mills are arranged, where possible, with all the card-room or preparation machinery on one floor. It is very usual to extend the ground floor by means of a shed extension along one side of the mill to enable this to be done. Usually the carding-engines are placed under this extension.

For fine counts, 120's to 140's, such as are now much spun in Oldham from Egyptian cotton, the card sliver is combed before being drawn, and the modern tendency is to use combs for even coarser yarns. Generally, owing to Indian competition, the tendency in Lancashire is all in the direction of finer counts.

Horse-Power to Drive Cotton Machinery, with Speeds for Pulley.

(Bolton figures.)

	I.H.P.	R.P.M.
Hopper bale breaker	2 to $2\frac{1}{2}$	450 to 500
Porcupine opener	2 to $2\frac{1}{2}$	800

Drum winder	1 h.p. „ 100 drums	400 to 600
80-hank reel	$\frac{1}{8}$	250

The power required tends to be more or less according to the speeds of spindles, beaters, etc. For finer counts spindles run at higher speeds, but machinery generally is lighter.

Electrical Driving of Cotton Mills.

The load factor of a cotton mill is probably 90 to 95 per cent. This renders electrical driving of doubtful economy. It cannot be economically done from an outside power station, for this would be doing well if it had a 40 per cent. load factor. A cotton mill with its own generating plant can work more cheaply than by purchased current at a price that would pay an outside power station to charge. Then the transmission line is costly.

A group of mills within a small radius such as may be found in places might perhaps be economically driven from one central power house close to all the mills. But in electrical driving the generator is more costly than the rope rim, and the motors, if on line shafts, are more costly than the driven rope pulleys. The transmission losses and the generator and motor losses appear to be greater than the loss by rope driving, and where each machine has its own motor this and the transmission system seem to cost much more than shafting and pulleys. Where the motor stands on the floor at the end of a spinning or speed frame it compels the cutting out of several spindles, reducing the output capacity several per cent., or by fully as much as it is claimed each spindle will give an increased output as compared with an ordinary mill. But so far this increased output has been only demonstrated as between modern high-speed engines with electrical driving and old slow-speed engines in some out-of-date rope-driven mill. No comparisons are put forward with modern rope-driven mills with modern high-speed engines.

There are two systems of electric driving : (*a*) with the usual line shafts, each shaft with an electric motor taking the place of the usual rope pulley; (*b*) with motors to each machine. And there may be (*c*) a mixed system on which there are line shafts for certain classes of work and separate motors for other machines. Rapid acceleration is claimed as an advantage of electrical driving. This, of course, demands motors much larger and more powerful than are merely necessary to drive the frame at its normal speed. The same acceleration may be secured with belt driving if the belts are made sufficiently larger than they need to be for the constant normal speed. Shafting does not require very much power to drive it, and where machine such as ring frames are closely spaced under a shaft, as are ring frames, it is difficult to see much benefit from electric driving of these machines, which do not stop until the bobbins are full. But with speed frames which must stop for every broken sliver it may be convenient that each machine should have its own motor. Mules which have an enormous and rapid variation of driving torque are badly suited for separate motors, and appear better driven from a line shaft. Given sufficient belt power any machine can be accelerated as rapidly as desired, and no single machine will be felt by the main engine any more than if accelerated electrically.

The abolition of belts is an advantage of some value in the separate motor system, but so far the experience of electrical driving has not been such as to warrant other than the most careful consideration of each case on its merits, and by an engineer who is a textile man first and an electrical engineer second. The following are estimates of cost of rope and electrical driving which may help the consideration of any particular case. The estimates are based on the driving of a 110,000 spindle mill (Bolton-fine-Counts) : (*Elec. Review.*)

Coal for heating, 300 tons at 12*s.* 6*d.*	188	0	0
Wages: Engineer, 55*s.*	137	10	0
Oil, waste, general stores	50	0	0
Insurance: motors, £60; transformers £15; gearing, £40; buildings, £10	125	0	0
Interest and depreciation on £9,280 at 12 per cent.	1,112	0	0

(*c*) *Running Costs*—continued.

Current: average load 900 k.w., including lighting, based on uniform charge of 0·5625*d.* per hour	5,906 0 0
	£7,680 10 0

Equal to 0·657 pence per k.w. hour.

From the foregoing it would appear that if current can be bought for about 0·4*d.* per unit the driving by a public supply would cost the same as by ropes.

In the foregoing estimates of running costs, the boiler cleaning charges are omitted, the extra cost of this for (*a*) and (*b*) being about balanced by the omission of the wages of the stoker of the heating boiler in case (*c*). It is at present doubtful if current can be sold at a profit for 0·4*d.* per unit by any power station. The situation is made worse by the necessity for a heating boiler and chimney, &c., for case (*c*).

On the other hand driving electrically disperses with the rope race which divides a mill halfway across into two sections, and it sets free the area of the race for machinery and increases the production within a given total area. But the real success of the system would come where a group of mills could be driven from a joint-power plant in the middle of the group, especially if the warming could be done from the same boilers. There is very little in the claim for steadier driving, this being merely a question of flywheel energy and cyclical regularity equally obtainable with ropes as electrically. No weight must be given to comparisons with old mills driven by old slow engines. Engineers should study the Brown Boveri ring frame, for which electricity does what is otherwise impracticable. In this machine the spindle speed is varied by moving the brushes of the motor so that the tension on the yarn is kept uniform at all stages of the bobbin. This cannot be done except by electrical means.

OIL MILLS.

The Manufacture of Vegetable Oils.

In the 'Anglo-American' system, the rolls are constructed 4 or 5 in height, allowing the seed to pass between each, thus getting 3 or 4 different crushings, each exceeding the previous one in weight.

The presses have plates with open sides, holding 12 to 18 cakes, this large number being made possible by the use of a cake-forming machine, which compresses the meal into a firm cake, capable of being passed between the press plates, though the latter are only about 3 ins. apart; the horsehair wrappers are also dispensed with.

A small self-contained mill of the foregoing type has a capacity of 50 tons of seed per week of 132 working hours, and consists of the following machines and parts:—1 set of seed crushing rolls with four chilled cast iron rolls, each 12 ins. diameter by 15 ins. long; 1 meal heating kettle, 42 ins. diameter by 20 ins. deep, constructed of mild steel, steam jacketed on sides and bottom and provided with an improved moistening apparatus and automatic outlet; 1 cake-forming machine with a steam compresser; 2 hydraulic cake presses, with rams 12 ins. diameter, working pressure 2 tons per square inch, with steel cylinder and steel press plates, each press to make 16 cakes per pressing; 1 belt-driven cake-paring machine to trim off the oily edges from the cakes and chop them up into small pieces; one reducing mill to grind up the edges cut off by the paring machine so that they can be passed back to the kettle and re-pressed; 1 set of hydraulic press pumps, with the necessary valves, pressure gauges and pipes.

The mill may preferably be fitted with elevators to raise the seed to the crushing rolls, and the ground meal to the kettle: also an oil catching and settling tank, a rotary oil pump to take the oil to the store tank, and all that is necessary to put the mill into complete working order.

For mills of larger capacities the machines are generally built separately, and the gearing carried from the walls of the building, columns, and floors. The mills are then fitted up in sets and double sets, with a capacity of 100 or 200 tons of seed per week of 132 hours. One set consists

of:—1 set of seed rolls, 5 ft. high, 16 ins. diameter by 48 ins. long; 1 heating kettle and cake-forming machine; 4 hydraulic presses, with rams 16 ins. diameter, working pressure 2 tons per square inch, each making 16 cakes per pressing; 1 cake-paring machine; 1 set of edge stones to grind up the parings, diameter of runners 4 feet; 1 hydraulic press pump.

These large plants are generally fitted with 2 hydraulic accumulators, working at 500 lbs. or 600 lbs. per square inch, and at 2 tons per square inch. The ballast of sand, scrap iron, etc., is held in a wrought-iron case, and is guided between wrought-iron guides. The sizes generally adopted are 9 ins. and 3 ins. by 8 ft. stroke for the small plants, and 14 ins. and 4 ins. by 10 ft. stroke for the large plants.

For seeds, etc., which contain a large percentage of oil, such as copra, palm kernels, arachides, castor, etc., 'Stake' presses have been introduced. The pressing cage is constructed of narrow steel bars bound together by weldless steel hoops, spaces being left between each bar to allow a free escape of the oil, but retaining the meal. This gives a much larger drainage area than can be obtained by perforations, and is not open to the same objections, viz. that the perforations wear larger and cannot be altered, so that the meal begins to escape in large quantities with the oil.

A filter press is used to remove the floating particles of solid matter. This is composed of a number of plates with grooves on their faces. Between each plate are placed two filter-cloths fixed of the plate in such a manner that the oil must pass through the cloth and flow down the grooves to the outlet provided. The oil is pumped through the press by means of a pump fixed to the machine, or by a separate pump which can be made to feed several. Another form of filter is made by fixing a large number of bags to openings in a shallow trough or tank; these bags are about 4 ins. diameter, 3 ft. to 5 ft. long, and are made of canvas; the oil filters through the material, leaving the impurities in the bag. A second trough is placed under these openings to catch the oil as it runs out.

CANE-SUGAR MACHINERY.

For large sugar works, the canes are brought from the field to the factory by rail in trucks which are weighed and unloaded mechanically on to a carrier which continuously conveys them to the

Crushing Mills.

These usually comprise a pair of cast steel preparing rollers followed by several sets of cast iron three-roller crushing mills in tandem, and steam driven through heavy spur gearing.

The cane in transit through these successive mills is macerated with hot water, enabling ordinarily a juice extraction of 80 per cent. on the weight of the cane to be obtained. This crushed cane (technically termed megass or begasse), leaving the final mill with 45 to 50 per cent. of contained moisture, is continuously fed into special boiler furnaces and utilised for steam generation, supplying frequently the entire factory requirements.

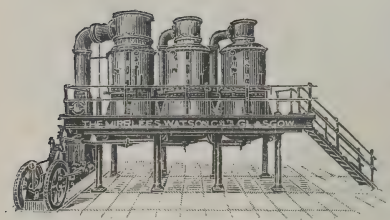
36×84	51½	64	38×72	34×60



The mill capacity varies according to the class of cane crushed.

Vacuum Evaporators.

The cane juice expressed by the mills is clarified (by liming, heating, subsiding, and filtering) and then concentrated, in vacuo, to about one-fourth its original volume. The apparatus commonly used is a triple or quadruple effect, in which exhaust steam is used as the heating agent for the juice in the first vessel, whose vapour, under a reduced temperature, boils the partly concentrated in the second vessel, which again liberates vapour for boiling the still denser juice, under a still lower temperature in the succeeding vessel, which, in the case of a triple apparatus, is under a high vacuum and consequently low temperature. In a quadruple effect the principle is similar.

ECONOMY OF MULTIPLE-EFFECT EVAPORATION.

1 lb. of steam used	single	effect evaporates	$\frac{7}{8}$	lbs. water.

Vacuum Evaporators for Trade Liquids.

In the concentration of trade liquors by evaporation, it is generally important that this should be not only economically but also rapidly effected under low temperature, as many liquids exposed to heat deteriorate. Hence the extended adoption of multiple-effect evaporators on the horizontal tube type of the Mirrlees Watson Co. Ltd., which, having a rapid flow of liquid through their evaporating tubes, meet these requirements with the minimum of deposition on the heating surfaces.

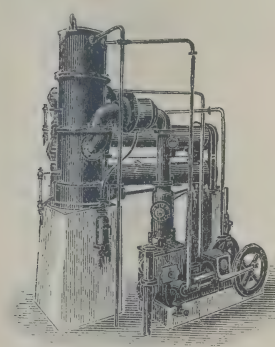

FIG. 4.—Double Effect.

For bark and wood extracts, gelatine, glue, glucose, glycerine, and similar liquids of a viscid nature, a wide temperature difference between the vessels is desirable, hence the use of a double effect arrangement (fig. 4); their sizes range from 50 to 1,000 gallons hourly.

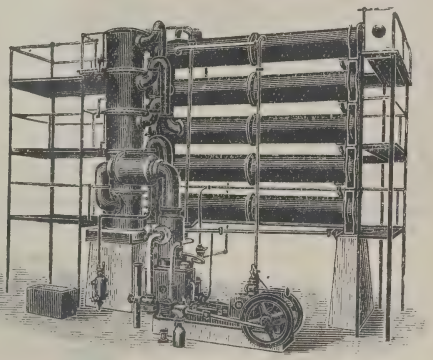

FIG. 5.—Quintuple Effect.

For soda ash recovery in paper mills, caustic soda, caustic potash, meat extract, distillery refuse, and other liquids readily amenable to concentration, triple, quadruple, quintuple (fig. 5), and sextuple (fig. 6) installations are in use; their sizes range from 100 to 3,000 gallons hourly.

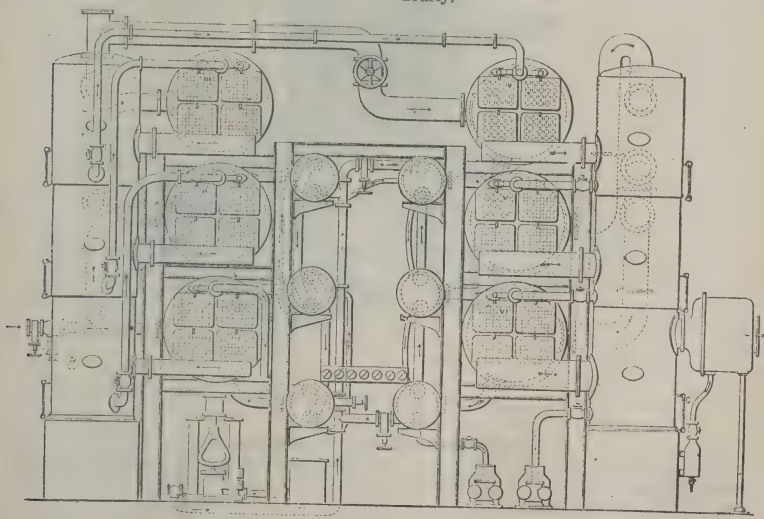

FIG. 6.—Patent Sextuple-Effect Evaporator.

Fig. 6 shows sextuple-effect apparatus as used for all glutinous solutions, such as gelatine, glue, etc. : they are mostly of the undermentioned capacities :—

STANDARD VACUUM EVAPORATORS FOR GLUTINOUS SOLUTIONS.

No.	Galls. Treated per Hour.	Galls. Evaporated per Hour.

6	200	160
7	230	184
8	260	208
9	290	232
10	320	256

Varying number of effects are used for different liquors, to meet requirements.

Water Distillers.

To meet the demand for large quantities of distilled water at the lowest cost, the Multiple-Effect system of evaporation, extensively used in sugar manufacture, has also been applied largely, by the Mirrlees Watson Co. Ltd., to fresh-water distillers.

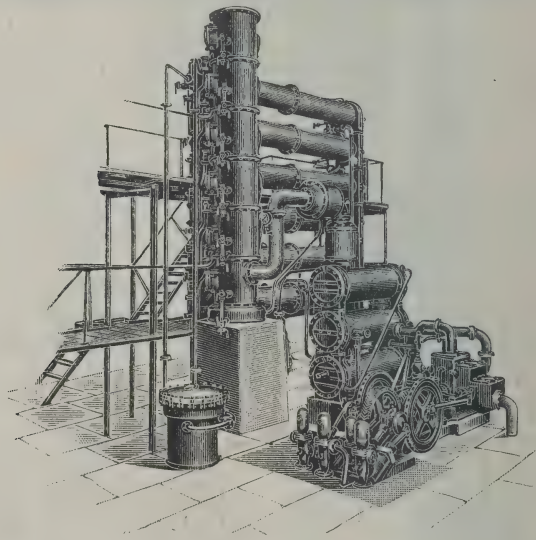

FIG. 7.—Fresh-Water Distiller.

THE MULTIPLE-EFFECT EVAPORATOR.

This consists of two or more vessels arranged in such a manner that the vapour arising from the evaporation in the first vessel effects the evaporation in the second, that from the second, evaporation in the third, and so on.

The principle on which the multiple-effect evaporation is based is that the boiling point, and consequently the vapour temperature of liquids, varies with the surrounding pressure; the lower the pressure, the lower the boiling temperature; this principle is applied by working with diminishing pressures in the successive vessels of the multiple-effect evaporator.

Evaporators on the above principle are extensively used, but considerable experience is required so to proportion the various evaporating and condensing surfaces to secure the highest economy.

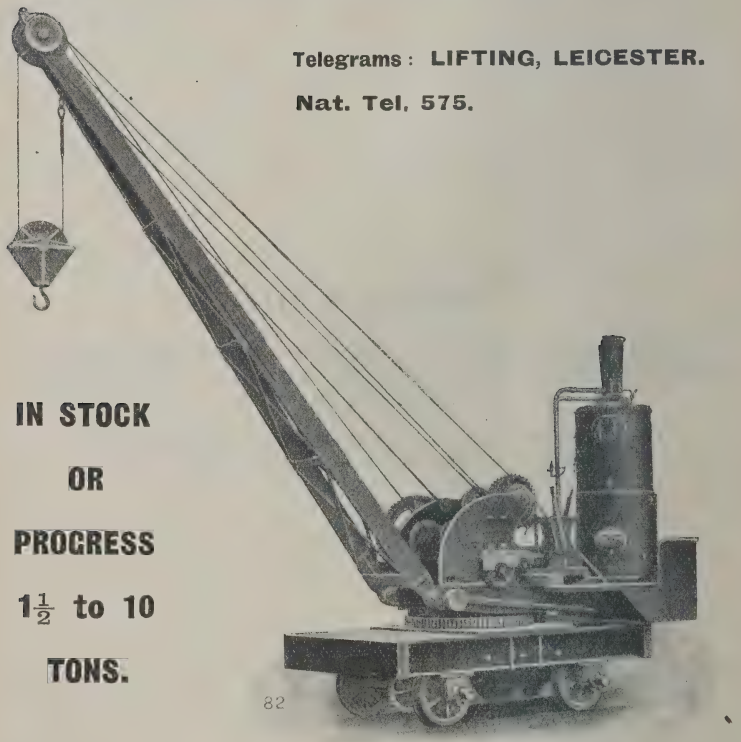
Fig. 7 shows a sextuple-effect fresh-water distilling plant, which has been brought to a high state of efficiency, producing 44 lbs. of gained water (not including the drip from first vessel, which goes back direct to the boiler) per lb. of coal consumed.

Plants of this design are made to produce from 25 to 350 tons of distilled water per twenty-four hours. This type of distilling plant has been adopted by the British and other Governments.

(*Mirrlees Watson Co. Ltd.*)

Note on Condensers.

Great caution should be exercised in guaranteeing the efficiency of condensers which are used for other purposes than the condensation of exhaust steam from steam engines, as for example the exhausting of vacuum pans for sugar manufacture. In such cases it often happens that far more air is present than is the case with ordinary exhaust steam, and consequently the condenser may prove unequal to the task for which it was guaranteed. Those who quote prices or guarantee a particular efficiency in the case of a condenser should make it plain that the 'steam' to be condensed must only contain a certain (specific) quantity of air.



SECTION XVII

CRANES AND CRANE APPLIANCES — ELECTRIC LIFTS — ELECTRIC WINDING ENGINES — AERIAL ROPEWAYS — CONVEYORS

CRANES.

Contributed by John H. Huntley, M.I.E.S.

General Notes on Cranes.

The selection of a crane for any particular service is governed by several factors, such as load, space available, power at disposal of user, frequency and speed of operation, height of lift, duration of service and cost.

Cranes can be operated by manual, steam, hydraulic, pneumatic, or electric power, or by a combination of these powers.

In power stations, stores, and places where an occasional lift is all that is required, a hand crane is quite suitable, even for loads up to 20 or 30 tons, but for frequent operation, or where the load has to be moved a considerable distance, it is advisable to instal a power-driven crane, even for a load of a few hundredweights, as the saving in time and labour soon pays for the difference in initial cost.

The electric crane has the following points in its favour :—

1. Simplicity of operation.
2. No power consumed whilst crane is standing.
3. Power used varies in proportion to load.
4. Always ready for starting up.

The steam crane has the advantage that it can be used wherever a supply of fuel and water is available, but time is lost in raising steam, and fuel is consumed in keeping up steam between the lifts.

Hydraulic cranes are only economical in operation when constantly working under full load, as the water consumption is the same for light or heavy loads, although by means of double-power rams attempts have been made to overcome this defect. Trouble is caused by frost in exposed situations. Hydraulic cranes are still largely used in shipyards and boiler shops, for handling plates, portable riveters, etc., where a small lift at slow speed is required. The working hydraulic pressure is usually 1,500 lbs. per sq. in., but may be as high as 2 tons per sq. in.

Pneumatic power is applied only to small hoists and pulley blocks, the air pressure being usually about 100 lbs. per sq. in.

Hand Cranes.

The ordinary height of handle above ground should be 3 ft.; radius of circle described by handle, not more than 18 ins.; 16 ins. is a usual length. Angle of jib, 45°.

Each man working at the handle of a crane will exert a force of 15 to 20 lbs., exclusive of friction.

If W = weight to be lifted by crane in lbs., P = force applied to handle in lbs., D = diameter described by handle in inches, n = number of revolutions of handle to one of barrel, B = diameter of barrel in inches, then

$$B = \frac{D \times P \times n}{W}. \qquad D = \frac{W \times B}{P \times n}. \qquad n = \frac{W \times B}{D \times P}. \qquad P = \frac{W \times B}{n \times D}. \qquad W = \frac{P \times D \times n}{B}.$$

OVERHEAD TRAVELLING CRANES.

For service inside buildings or where the site conditions permit of the construction of a gantry the overhead travelling crane has proved to be the most efficient appliance. For outside work a Goliath crane is often equally serviceable, and has the advantage of a lower first cost than an overhead crane with gantry.

For hand cranes up to 40 ft. span and loads up to 5 tons, a single girder crane can be adopted, but for longer spans or heavier loads it is advisable to use the double girder type to obtain lateral stiffness.

Light cranes are usually operated from the floor level by hanging chains, but for cranes above 10 tons it is advisable to work them from the crane platform. The pull on a hand chain should not exceed 40 lbs. per man, and for crank handles not more than 25 to 30 lbs. per man. The handles should have a radius of 16 ins. to 18 ins. and the centre be at a level of from 2 ft. 6 ins. to 3 ft. above platform level.

Travelling wheels for both crab and crane are usually of cast iron, and should be fitted with ball or roller bearings.

The hoisting gear should be efficient, preferably with machine-cut teeth, pinions of mild steel, wheels of cast iron, and should be fitted with a self-sustaining brake which requires to be released by the operator before the load can be lowered, but which is inoperative in the hoisting direction. This condition can be obtained by an internal ratchet or a screw disc brake.

Worm gear should have a coarse pitch and the sustaining power of the crane should not be dependent upon the inefficiency of the gear.

OVERHEAD ELECTRIC CRANES.

For engineering shops, foundries, steelworks, etc., the overhead electric travelling crane is unequalled for general service.

The motions of hoisting, traversing and travelling are generally arranged, and a separate motor should be fitted for each motion. An auxiliary hoist having a lifting capacity of about one quarter the main hoist is desirable on cranes above 40 tons capacity, and should be operated by an independent motor.

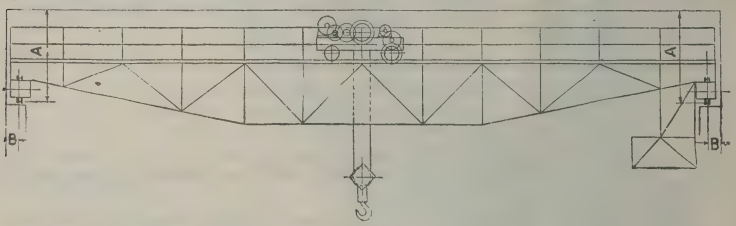

FIG. 1.

The following are particulars of standard 3-motor overhead travelling cranes (fig. 1), 30 ft. lift :—

NOTE.—The headroom figures allow for about 3 ins. clearance and the end space for about 1½ in. clearance.

For short-span cranes of small size, a pair of 'H' beams make an economical set of girders, but the span should not exceed sixty times the width of the flange of one girder. For cranes up to 60 ft. span the most economical construction is the trapezoidal single web girder, with lattice auxiliary connected to the main girder by horizontal and diagonal bracing. This makes a very stiff construction, is easy to manufacture, and all surfaces are accessible for painting. The platform and travelling gear can be well supported by bearers between the main and auxiliary girders. For long spans and for outside service it is desirable to make the girders of the lattice type to reduce weight and wind surface. The depth of the girder is usually made one-twelfth the span. The maximum bending moment due to the crab, assuming each wheel equally loaded, is given by the formula :—

$$\frac{W}{2S}\left(S-\frac{B}{2}\right)^2 \text{ ft. tons,}$$

where,

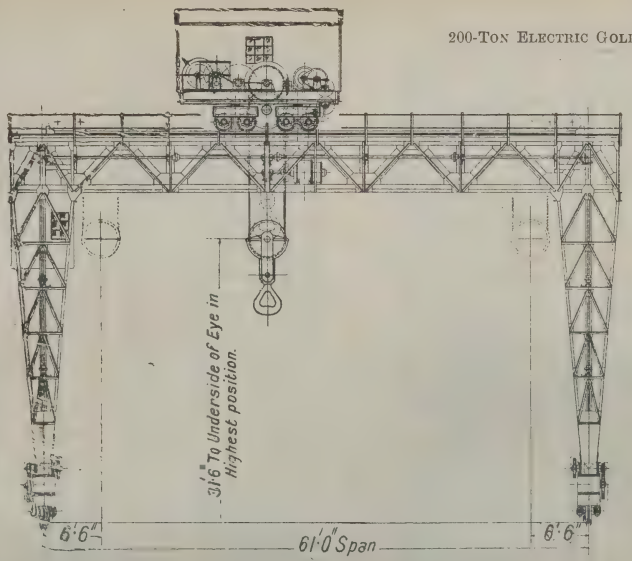
W = load per wheel in tons ; S = span in feet : B = wheel base of crab in feet.

To this must be added the bending moment due to the deadweight of the girder and travelling gear. The modulus of the girder section should be such as to give a stress of between 5 and 6 tons per sq. in. The stresses in lattice girders are best determined by graphic methods.

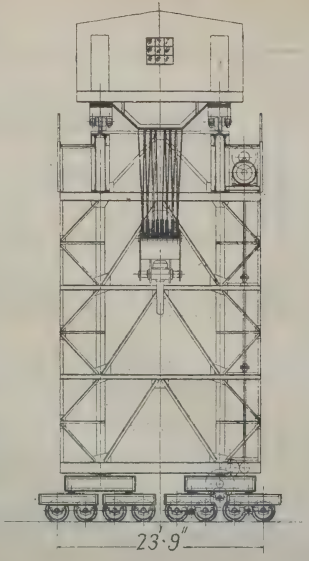
The end carriages can be constructed of channels, and built up of plates and angles, when larger sections are required. They should be connected to the girders by large gusset plates, and fitted bolts to prevent cross winding. The wheel base should preferably be one-fifth to one-sixth of the span.

Rail wheels should be of cast steel, or of cast iron centres with steel tyres shrunk on. The width of the rolling surface of the rail is an important point, and for heavy loads a rounded surface should be avoided. The safe load on a wheel may be arrived at by the following empirical ormula :—

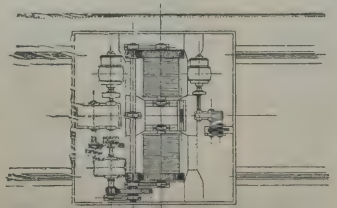
For cast steel wheels, safe load in pounds = $800 \times W \times D$,
,, steel tyred ,, ,, ,, ,, = $1{,}200 \times W \times D$,



where,



W = width of rail face in inches ; D = dia. of wheel in inches.



Rails for heavy cranes are now rolled with a working face of 6 ins. and weight of 265 lbs. per yard.

Cranes of 75 tons capacity and upwards are usually mounted on eight wheels, four in each end carriage. The wheels are carried in pairs by equalising beams pivoted to the end carriage so as to distribute the load equally to each wheel of the pair.

200-Ton Electric Goliath Crane.

5-TON 2-MOTOR ELECTRIC GRABBING CRANE

F. 787

To calculate the power required to travel a crane, a tractive force of from 60 to 70 lbs. per ton is usually taken, and for outside service the effect of wind pressure must be considered.

To prevent cross winding the cross shaft should be stiff enough to avoid undue torsional deflection when the driving wheels are unequally loaded due to the crab being at one end of the span. A foot brake should be fitted to the cross shaft on cage control cranes and a solenoid brake fitted to the motor shaft on all cranes working in the open.

The crab frame should be built up of steel sections well stiffened to form a rigid support for the motors and gearing. The traversing wheels should be of cast steel or have steel tyres, the latter only being necessary on crabs of the largest size.

It is unnecessary to fit a brake to the traversing motion unless the speed exceeds 100 ft. per minute, when a solenoid brake can be fitted.

The load is preferably lifted on wire ropes winding on to a cast iron drum rotated by gearing, the number of falls of rope depending upon the load. For cranes up to 3 tons capacity, the load may be lifted on two falls winding one fall on to the barrel. Where four or more falls of rope are used, two falls should wind on to the barrel, which should have right and left-hand spiral grooves and thus keep the load central between the girders.

The efficiency of the gearing varies from about 75 per cent. on small cranes to 65 per cent. on large cranes. A convenient rule to determine the horse-power of the motor is

$$\text{H.P.} = \frac{\text{foot-tons per minute.}}{10}$$

The speeds of working given in the foregoing table are suitable for general engineering shop work, but for steelworks very much higher speeds are used, and as continuous night and day service is the general practice in these works the design of the crane should be specially considered and made very robust.

All cranes are preferably fitted with two brakes, one of which should be an automatic solenoid brake; the type of the other brake will depend entirely on the service for which the crane is used.

Fig. 3 shows a small crab made by Messrs. Babcock & Wilcox. The framework consists of mild steel plates or channels connected by stretchers which support the motors and the return sheaves of the hoisting ropes. The hoisting motor (8) is fitted with an extension shaft (9) on which is fixed the automatic magnetic brake (10). Two blocks press against the face of the brake pulley by means of a counterweight (50), when the crane is standing. When current is switched on, the weight is lifted by the action of the solenoid, and is automatically reapplied when current is cut off. There is also a mechanical brake (12), operated from the cage by a foo pedal attached to a lever. This lever is connected to the flexible wire (15) stretching from end to end of the cross-girders and passing over two fixed pulleys (16) and under a movable pulley (17) coupled to a counterweight (20) which serves to keep the brake strap clear of the brake-wheel. By operating the pedal the brake strap can be tightened round the brake-wheel.

The hoisting motor extension shaft (9) carries two sliding pinions, one for slow and heavy hoists (21), and the other for quick and light hoists (22), and these may be put into gear by means of a lever operated by hand from the driver's cage when the crab is opposite to it. These pinions gear with spur wheels (23) and (24) on the first motion shaft which carries the mechanical brake (12). At the farther end of this shaft, a pinion gears into the spur wheel (27) on the second motion shaft. On this latter shaft, another pinion gears with the main spur wheel (30) which is bolted to the hoisting barrel (31). The two ends of the hoisting rope are secured to the ends of this barrel, which is grooved right and left-handed, so that the rope on each side is wound uniformly towards the centre and a truly vertical movement given to the lifting hook. An overwinding gear is fitted consisting of a screw spindle and travelling nut which, when the hoisting hook has reached its highest position, strikes a lever connected to an emergency cut-out in series with the hoisting controller and motor. This action opens the switch, cuts the current off the motor and applies the magnetic brake, thus stopping any further winding. With D.C. motors the hoisting controller is fitted with rheostatic brake steps to control the load when lowering. With A.C. motors hand gear is used to release the magnetic brake mechanically. This gear consists of a lever attached to a flexible wire (61), stretching from one end to the other of the cross-girder, passing over two fixed pulleys (62) and under a movable pulley (63), fitted with the counterweight (50). By operating the lever, the movable pulley and weight may be raised, thereby freeing the brake to any desired extent.

On the spindle of the traversing motor (40) a pinion is fitted which gears with a spur wheel keyed on to the first motion traversing shaft (43). By means of another pinion and spur wheel this shaft is connected to the driving axle (46) to which are keyed two of the wheels (47) on which the crab runs. The remaining two wheels (48) are keyed to the trailing axle (49) which runs freely in its bearings.

For handling hot ingots in rolling mills, special cranes with semi-automatic tongs are used and have been made to fulfil such varied functions as stripping the ingot from the mould charging and withdrawing the ingot from the soaking pit, and lifting and replacing the soaking pit cover.

Grangefield Works,
Stanningley, nr. Leeds

For handling molten metal, special cranes known as 'ladle cranes' have been designed, and are made up to 150 tons capacity, but cranes of 80 to 100 tons are more generally used. These cranes are fitted with two crabs, the main crab running on top of the girders and the auxiliary crab between the girders and on the lower flanges. The main crab has two barrels arranged so that the hoisting ropes pass outside the girders to sheaves attached to a lifting beam from which the ladle is suspended. The auxiliary crab has usually a lifting capacity of about 20 per cent. of the main crab and serves for general lifts and for tipping the ladle if required.

For handling forgings under hydraulic presses, special cranes have been developed with relieving gear to prevent overloads due to the action of the press in pulling down a forging which is suspended not quite level with the anvil. These cranes are made up to 200 tons capacity, and can be fitted with detachable gear for rotating the forgings.

For stores, warehouses, and machine shops an overhead travelling crane with underhung jib has many advantages owing to the increased area covered by the jib.

For outside service the Goliath crane fulfils the same function as an overhead traveller, and eliminates the gantry. Fig. 2 (p. 786) shows a crane of this type designed for lifting loads up to 200 tons.

The speeds of working and sizes of motors are:—

Hoisting, slow gear	200 tons,	3 ft. per min.	Motor 65 h.p.
,, fast ,,	75 ,,	8 ft. ,,	
Traversing	200 ,,	30 ft. ,,	,, 25 ,,
Travelling	200 ,,	50 ft. ,,	,, 65 ,,

The load is lifted on sixteen parts wire rope, winding one part on to each of two barrels rotated by the 65 h.p. motor through four reductions of gearing. Change-speed gear is provided for handling loads up to 75 tons at a quicker speed. An automatic solenoid and automatic mechanical brake are fitted, the latter working entirely enclosed in an oil box. The crab is mounted on four two-wheeled bogies and traversed by the 25 h.p. motor driving four rail wheels through four reductions of gearing. The crane travels on a twin rail track, there being eight centre-flanged steel-tyred wheels under each leg. Four wheels on each side of the crane are driven. The girders are of the lattice type with auxiliary girders and bracing to give lateral stiffness. All motions are operated from an enclosed cabin situated in an elevated position; the hoisting and travelling controllers are of the contactor type and the traversing of the drum type.

Overhead Runways.

Overhead runway systems, consisting of a track formed from a single rolled-steel joist which may be curved to suit local conditions, and have switches or turntables, are frequently installed in warehouses, steelworks, gas works, and other situations where an overhead crane is unsuitable or too expensive. Hand-pulley blocks and trolleys are used on the runways for occasional service and light loads, but for speed and loads up to five tons an electric trolley hoist should be installed. These may be either floor or cage controlled, and have usually separate motors for hoisting and travelling. The lifting speed may be as much as 100 ft. per minute, and the travelling speed from 200 to 800 ft. per minute, according to the duty required.

Grabs can be fitted to lift coal, ore, or similar material.

Derrick Cranes.

The Scotch derrick crane, largely used by contractors, has many advantages on account of its portability, simplicity of erection and long outreach. As commercially manufactured in stock patterns, these cranes have not usually a very large factor of safety, and if the full load is to be constantly handled it is advisable to specify a crane for about 25 per cent. greater load. Cranes of this type are specially made in large sizes for dock-side service in fitting out vessels under construction, but are giving way in favour of the more efficient cantilever crane.

Locomotive Cranes.

For general service on railway sidings around works and shipyards the locomotive steam crane is unequalled. These cranes are made in standard sizes up to 10 tons capacity and lift the load free on track with the jib in any position.

The following table gives particulars of standard steam cranes manufactured by Messrs. Samuel Butler & Co., Ltd., of Stanningley:—

Standard Locomotive Steam Cranes, 4 ft. 8½ in. Gauge.

Size.	Radius.	Size of Engines. (Cylinders.)	Size of Boiler.	Steam Press.	Speeds.			Weight.
					Hoist, f.p.m.	Slew, r.p.m.	Travel, f.p.m.	
Tons.	Ft	Ins. Ins.	Ft. Ins. Ft. Ins.	Lbs.				Tons.
3	16	7 by 10	7 9 by 3 6	100	80	2½	350	14½
5	16	8 by 10	8 3 by 4 0	100	80	2½	350	22½
7	16	8 by 12	8 3 by 4 0	100	50	2	300	32½
10	16	9 by 12	9 0 by 4 0	100	40	2	250	45
15	16	9 by 12	9 0 by 4 0	100	40	1½	200	54

For cranes of longer radius or greater lifting capacity than the above, blocking girders and rail clips are fitted to give the necessary stability, or the cranes may be made heavier.

Cranes that are to travel round sharp curves should have sliding axle gears or differential gears and the conditions pointed out to the crane makers at the time of ordering.

The travelling gear should be of steel, also the slewing ring and pinion.

The slewing spur-ring forms the roller path and should rest on a machined seating on the truck, the pressure of the slewing rollers being sufficient to hold it in position for normal working, but in the event of sudden loads it will slide sufficiently to absorb the shock and prevent damage to the gearing.

The engines are usually of the double cylinder non-condensing type, cranks at right angles and cut off at about three-quarter stroke. The boiler is of the vertical cross-tube type for a working pressure of 80 to 100 lbs. per sq. in. and should be lagged. Two means of feed should be fitted and the incoming water should enter above the firebox, and not impinge directly on the heated plates.

The mountings should preferably be flanged, and secured by studs to pads riveted to the shell of the boiler, rather than screwed directly to the shell. The safety valve should be separate and not a combined mounting with the stop valve.

A list of standard boiler mountings would consist of :

1 steam-pressure gauge with syphon ;
1 water gauge with plate glass protection ;
1 spring loaded safety valve ;
1 steam stop valve ;
1 injector with steam cock and feed check valve ;
2 test cocks ;
1 steam jet cock and pipe to funnel ;
1 blow-off cock.

The feed pump may be either a steam donkey pump or be driven direct from the engine crosshead.

Steam Breakdown Cranes

for use on the permanent way, have been made up to 100 tons lifting capacity, but in Great Britain the usual size is from 10 to 35 tons. The truck of these cranes is provided with the usual permanent-way fittings and the axles are spring borne. The maximum load per axle with the crane in running order should not exceed 18 tons. When the crane is ' in train ' the travelling gear should be disconnected and the superstructure locked to prevent it turning. Owing to the limited space due to the crane having to clear the loading gauge, a comparatively small size boiler must be fitted, and this should be of the multitubular type as the ordinary cross-tube boiler would not generate enough steam.

Wharf Cranes.

For dock-side service in loading and unloading ships, the high gantry type of jib crane is principally used. The usual sizes are from 1½ tons to 5 tons and the radius from 40 to 60 ft. The gantry is made wide and high enough to admit of the passage of rolling stock underneath and to keep the jib clear of the sides of large vessels. A separate motor should be fitted for each motion.

Typical speeds of working, in feet per minute, are as follows :—

Description.	Size.		
	1½ tons.	3 tons.	5 tons.
Hoisting	200	150	120
Slewing	500	400	300
Travelling	100	100	80
Derricking	150	120	100

For high derricking speeds some form of compensating gear is essential to reduce the power consumption due to raising the load and jib each time the radius is reduced. With the ideal compensating gear the path of the load is kept horizontal as the jib is raised or lowered, and with the jib balanced the power required is only that necessary to overcome friction.

For handling coal, ore, and similar materials, much time and labour is saved by using grabs. These may be on the single or double-chain principle.

The single-chain grab may be fitted to any crane lifting on a single fall of rope, but grabs of the double-chain type require an extra drum to coil up the opening or closing rope. This should preferably be driven through a friction drive, although for short lifts a spring drum is quite suitable. Grabbing work is very severe on cranes and the nominal size of the crane should be 50 per cent. in excess of the combined weight of grab and contents. The empty grab may be balanced by sliding counter weights to reduce the power consumption.

Double rope grabs have a tendency to spin and twist the ropes round each other. This may be overcome by fitting two sheaves at the grab head, and leading the opening and closing rope back to the jib head or winch, the grab being thus suspended on three ropes spread apart by the sheaves, which keeps it perfectly steady. On heavy grabs two hoisting ropes are used either on the single or double chain principle.

SHIPBUILDING CRANES.

For service over shipbuilding berths, high gantries with overhead travellers and mono-rail cranes, gantries with cantilever cranes, steel derricks and tower cranes, are used, and experience favours the latter type.

Tower cranes may be either of the fixed or travelling type, practice in Great Britain being inclined to the fixed type, as they require less clearance between the berths, and use is made of valuable space which would otherwise have to be kept clear for the track of a travelling crane.

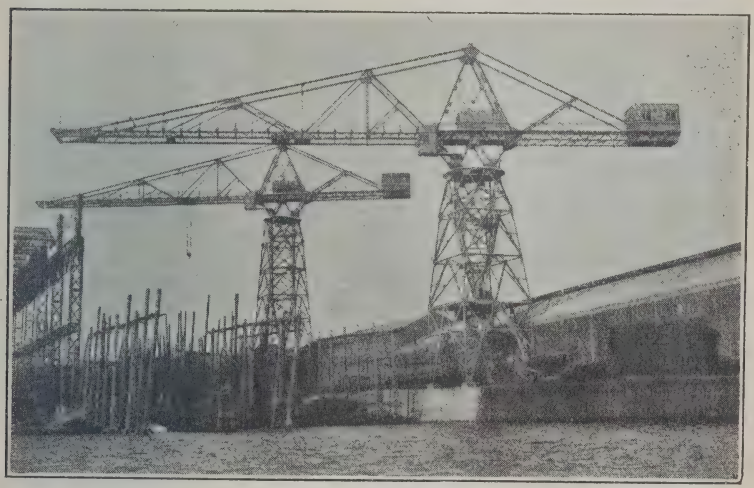

FIG. 4.—Tower Cranes.

Fig. 4 shows cranes of this type designed by Sir Wm. Arrol & Co., Ltd., Glasgow. The horizontal cantilever is designed as a track for a travelling trolley which carries the load hook. The motions of hoisting, slewing, racking, and travelling are fitted, operated by independent motors. The cranes are made with a lifting height up to 120 ft., and a radius up to 140 ft. The usual capacity is 5 tons at 100 ft. radius and 10 tons at 50 ft. Travelling cranes of this type have been made to lift 30 tons at 100 ft. radius, 15 tons at 140 ft. radius, and with a height of lift of 120 ft., but these are exceptional sizes.

For fitting out, cranes of the wharf type with derricking jibs are used, and range in size from 10 to 40 tons, with radii up to 80 ft., according to requirements. Two speeds of hoisting are

generally arranged, so that light loads may be lifted at a speed of 50 to 80 ft. per minute. A typical crane of this type lifts 30 tons at 55 ft., 20 tons at 72 ft., 10 tons at 80 ft. radius, and is mounted on a gantry to clear rolling stock, the centres of the gantry track being 22 ft.

For the same purpose floating cranes are occasionally used, and have the advantage of being transferable from dock to dock, but with them it is not easy to deposit a heavy load with precision, as the crane follows the movement of the water and its equilibrium is disturbed with every fluctuation of loading. These cranes are usually steam operated, but in recent years several large cranes have been electrically driven. This appears an unnecessary and expensive refinement, offering little advantage to compare with the additional cost of installing generators unless other use can be made of the power.

The pontoons are usually rectangular, flat-bottomed vessels, but if self-propelled it is advisable to give them a ship shape. The angle of heel under full load conditions and a 5 lb. wind should be not more than 5°. Travelling ballast is sometimes fitted to limit the heel under various loading conditions. Fig. 5 (p. 793) shows a 30-ton crane of this type constructed by Sir Wm. Arrol & Co. Ltd., Glasgow, for the Brazilian Government. It is designed to lift 30 tons at 10 metres outreach from the side of the vessel and is steam operated, the motions of hoisting, derricking, and slewing being fitted. The pontoon, built by Messrs. Ritchie, Graham & Milne, of Glasgow, is of the self-propelled type, 150 ft. long by 50 ft. beam by 8 ft. deep, and is fitted with two sets of compound surface condensing engines having cylinders 13 ins. and 26 ins. by 18 ins. stroke, to give a speed of seven knots.

The boilers are of the water-tube type and supply steam to the crane engines, auxiliary machinery and electric light set.

The Giant cantilever crane is adapted for loads from 75 to 250 tons and enables large portions of machinery, gun turrets, etc., to be lifted on board as a complete unit. A typical crane of this type, manufactured by Sir Wm. Arrol & Co. Ltd., Glasgow, is shown in fig. 6 (p. 793). The leading dimensions are :—

Max. radius for 250 tons	105 ft.
,, ,, ,, 120 ,,	130 ft.
,, ,, ,, 80 ,,	160 ft.
Height to top of tower	140 ft.
Base of tower	50 ft. square.

The main hoisting machinery consists of independent hoists each of 125 tons capacity, which can be worked together when required. The auxiliary hoist is of 40 tons capacity and the jigger hoist of 10 tons, this latter having a separate track and trolley on the underside of one of the cantilever girders. The crane was satisfactorily tested with a load of 360 tons.

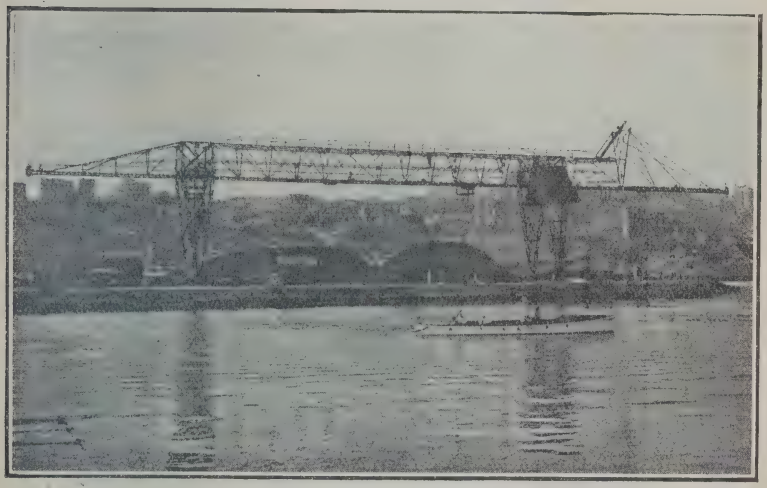
General Data.

Structures.

Crane structures should be made of open-hearth mild steel, 28 to 32 tons tensile strength, extension not less than 20 per cent. in eight inches. In determining the section of members, allowance should be made for the vibration due to the movement of the load and machinery, for the movement of the structure in the case of a travelling crane, and deflection should be considered where bearings for shafts are carried on structural members. The stresses should be such as to give a factor of 5 to 6 on the ultimate strength of the material. The ratio of length to radius of gyration should carefully be considered in struts, and charts plotted from Claxton Fidler's or Tetmeyer's formula form a reliable basis on which to determine the stresses. For wind bracings the factor of safety need not be more than three, as this is an exceptional loading infrequently applied.

Wind pressure on cranes in exposed positions in Great Britain may be taken as a maximum of 40 lbs. per sq. ft. It is inadvisable to work a crane in a wind pressure above 5 lbs. per sq. ft., and when designing the structure it is therefore unnecessary to allow for a higher pressure under full load conditions. The maximum wind pressure must of course be considered separately.

The revolving superstructure of jib or cantilever cranes may be carried on a ring of live rollers, or on a set of four or eight large diameter rollers designed as travelling wheels, but with conical treads and unflanged. The live rollers may be of either forged or cast steel and should run between two steel guard rings connected to the centre pin casting by radial rods. A gunmetal washer should be fitted between each roller and the outer guard ring, to take the outward thrust of the rollers. For unhardened rollers the pressure in lbs. should not exceed 400 by length in inches by diameter in inches. The roller-paths should be of steel, machined conical on the face to form a full bearing for the rollers.



On jib cranes up to about 5 tons capacity the rollerpath frequently consists of a flat-bottom rail bent to a circle, and the superstructure is then mounted on four rollers 15 ins. to 18 ins. diameter. This is a cheap and serviceable construction.

A friction clutch should be incorporated in the slewing gear adjusted to slip and prevent damage in the event of excessive shock due to too sudden application of the brake or the fouling of jib with some stationary object.

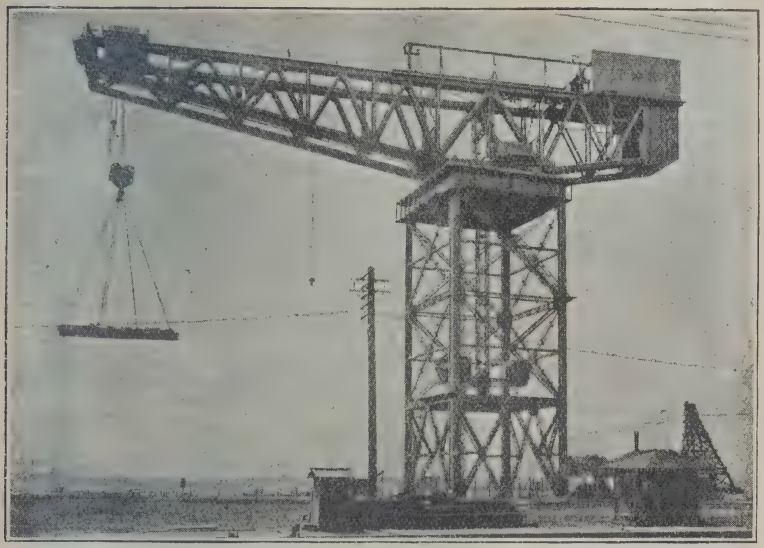

FIG. 5.—30-Ton Steam Floating Crane.

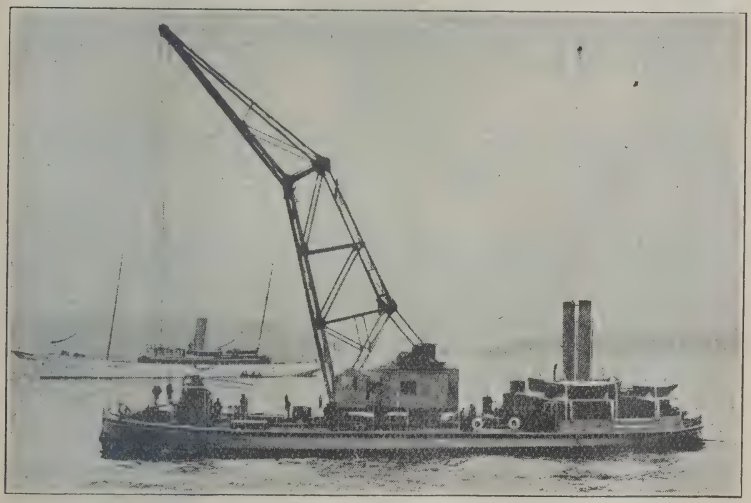

FIG. 6.—250-Ton Giant Crane.

Gearing.

On all high-class crane work the gearing should be machine cut. For hand and low-power cranes cast-iron wheels and steel pinions are satisfactory, but for all high-speed cranes the gearing should be of steel, with the possible exception of motor pinions, which, to ensure silent running, may be of rawhide, fabroil, or phosphor bronze.

For heavy loads and high speeds, machine-cut double helical gearing is very satisfactory, efficient, and silent.

The strength of spur gearing can be determined by the Lewis formula (page 877).

Worm wheels should consist of a phosphor bronze rim fixed on a cast-iron or steel centre, and have machine-cut teeth. The worm should be of high tensile forged steel and need not be hardened unless facilities exist for grinding the threads. In determining the size of worm gearing the heating effect must be considered as well as the strength.

Shafts.

In designing shafts the resultant loads should be determined and the effect of combined bending and twisting moments considered. The equivalent twisting moment due to combined bending and twisting is equal to

$$BM + \sqrt{(BM)^2 + (TM)^2},$$

where

BM = bending moment; TM = twisting moment.

Stresses should be low on account of the frequent reversal and impulsive loads common with crane work. Where keys are fitted, the shafts should be increased in diameter.

Bearings.

For cheap hand cranes the bearings are usually of cast-iron and not bushed. All power-driven cranes should have gunmetal bushed bearings. The bearing brackets should be fitted with caps, and the bushes be in halves. Studs for securing the caps are not desirable. Tee-headed bolts should be used, and these should fit in a slot accessible from the outside of the pedestal so that the bolts can be withdrawn after the cap is removed and without disturbing the steps. The pressure per sq. in. for shafts running at medium speeds should not exceed 600 lbs. For slow-moving pulleys and axles the pressure may be as high as 1,000 lbs. per sq. in. Fast-running shafts, such as motor spindles, should have ring lubrication. Axles are frequently fitted with float lubrication, which consists of a cylinder of wood floating in an oilwell formed in the inverted cap of the bearing and by contact with the axle supplying the necessary lubricant. Screw-down and spring-feed lubricators with grease are very satisfactory.

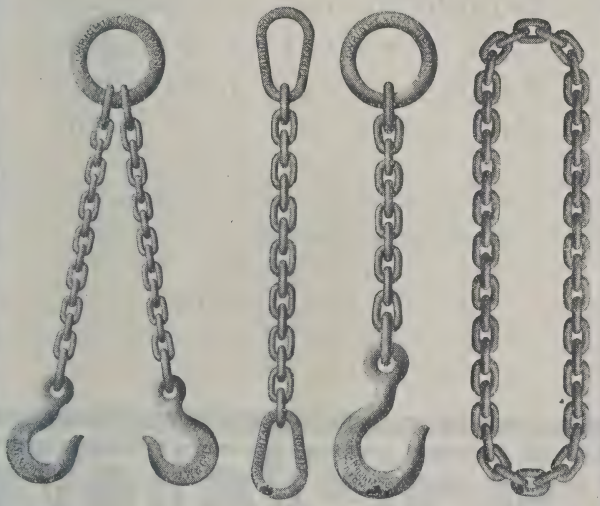
To reduce frictional losses, ball or roller bearings are sometimes fitted, and the makers should be consulted regarding the size of these. Ball bearings are very serviceable for worm thrust bearings, footstep bearings, and for under the hook.

Ropes.

Ropes for crane work should be of extra special flexible quality, 6/37 stranding if above 1¾ in. circumference, below this size 6/24 or 6/19 stranding. For ordinary work a hemp core is suitable, but where exposed to heat a soft iron core is desirable. The diameter of the barrel and pulleys round which the rope passes should be between six to seven times the circumference of the rope. For high speeds it is advisable to use even larger pulleys than given by this rule. Sharp and reverse bends should be avoided, although with single ropes which may twist in winding the effect of a reverse bend is problematical. When lifting on a single fall, a so-called 'non-twisting' rope should be used. Ropes made from very high tensile steel wire are stiff and tend to 'bird-cage' or open out. The rope, particulars of which are given on page 805, is recommended for cranes. Ropes should be lubricated and examined in service for broken wires and corrosion. The barrels and pulleys should be machine-grooved to form a smooth and even surface for the rope to bed on. Hoisting ropes should have a factor of safety of at least seven, and even higher with small size ropes.

(See also page 283.)

Chains.



Chains should only be used for grabs or situations where the fine strands of a rope would be damaged by abrasion. The working load for a welded iron chain is given by the rule

$$W = \frac{(\text{dia. of iron in } \tfrac{1}{4} \text{ in.})^2}{9}.$$

Weldless steel chains are about 33 per cent. stronger, and make good slings on account of their lower weight. Steel plate driving chains are sometimes used for drives instead of gearing, and give good results if properly designed. The burden chain for large ingot rotating gears is best constructed of one inner and two outer links connected by steel studs.

HOOKS.

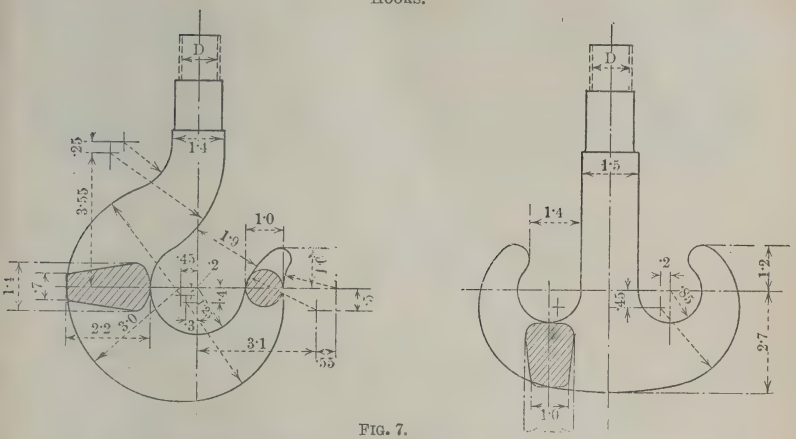

FIG. 7.

Fig. 7 gives proportions of hooks in terms of the diameter at the bottom of the thread. The size for any load can be arrived at by fixing the size of the shank to carry the load in tension. The area at the bottom of the thread must be taken. Hooks should be forged from mild steel.

Crane hooks depending from large travelling cranes in machine shops ought to be painted white, so as to be easily seen. With this improvement in visibility workmen will be less likely to run against a hook or to be struck by one which is moving.

THE DESIGN OF LIFTING TACKLE.

Fig. 8 shows a faulty design of eye-bolt, likely to break without warning; and fig. 9 one which would stand rough usage, permit a pull at bad angles, give way, and give notice before it broke, and at the same time possesses a useful strength (over 200 per cent.) beyond that of fig. 8.

These eye-bolts—hand-forged, of both types—have been tested to complete destruction at

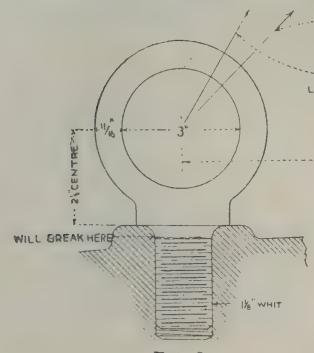

FIG. 8.

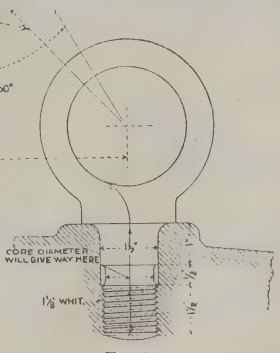

FIG. 9.

various 'punishing' angles, by Messrs. Kircaldy, and the verdict has been from 50 per cent. to 250 per cent. in favour of the fig. 9 pattern.

The arrows depict the form and direction of the strains, and such were precisely followed in the tests by Messrs. Kircaldy.

The increased strength as a result of decreased material, refers to the reduced part A, for this reduction is an effective factor which contributes to the need that the strain of the load should be distributed over as large a volume of the composition of the bolt as is possible.

(*J. W. Towlson, 'The Electrical Review.'*)

BRAKES.

One of the most important features on a crane is the brake, and this should have a large factor of safety. The brakes in common use are electric, automatic solenoid, centrifugal, automatic mechanical, and manual brakes. Hydraulic and pneumatic brakes are used for heavy loads, or where extremely fine control is desired.

A typical arrangement of a solenoid brake is shown in fig. 10. The brake is applied by

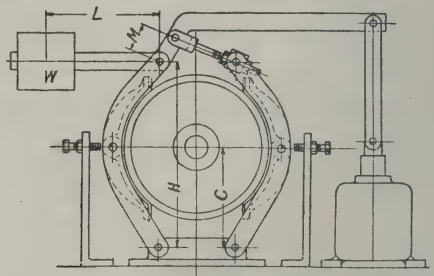

FIG. 10.

the weight and released by a solenoid magnet connected in the motor circuit so that it is excited immediately current is switched on to the motor.

If F is the turning force on the rim and μ the coefficient of friction between the brake shoe sand sheave, then the weight required to apply the brake equals

$$\frac{C \times M \times F}{H \times L \times 2\mu}$$

where C, M, H, and L refer to the dimensions shown in fig. 10.

The weight of the solenoid plunger and levers must be taken into account, and about 10 per cent. is usually added for friction in joints.

The centrifugal brake is designed to control speed, and does not serve to sustain the load at rest. In one form it consists of a series of weighted slippers which are pressed by centrifugal action on the inner rim of a fixed annulus, and thus have a retarding effect. The brake shoes should be slightly lubricated and ample radiating surface allowed to dissipate the heat generated

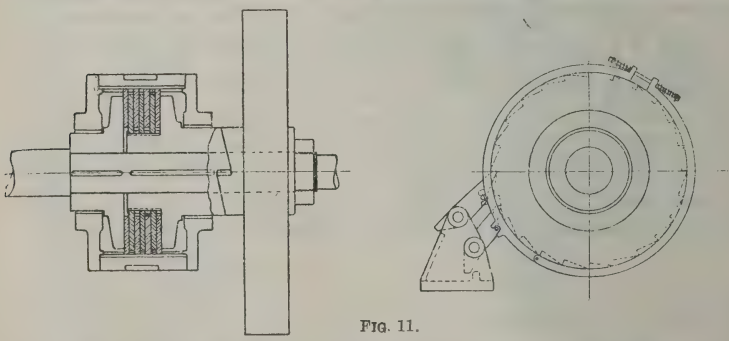

FIG. 11.

The automatic mechanical brake, known also as the 'Weston washer brake,' depends for its action upon the friction between a set of fixed and rotating discs. The pressure on the discs is obtained by a screw and nut, or two helical surfaces which set up an axial thrust along the brake shaft. Fig. 11 shows one type of this brake in which the friction discs, alternately of bronze and

steel, are enclosed in a cast-iron box, with ratchet teeth on the outside. One set of discs is connected by feathers to the box, and the other set to the thrust plate. The driving wheel has a helical face formed on the boss which engages with a corresponding face on the thrust plate. When hoisting, the discs are pressed up tight and the whole brake revolves, but when lowering, the pawls engage with the ratchet box, and hold it stationary. The pressure on the discs is relieved by the reversal of the motor, and the load is free to descend. As it tends to accelerate and gain on the motor, the discs are pressed together again and the friction between the surfaces of the fixed and revolving discs forms the braking effect. Ample lubrication and radiating surface are essential for the successful operation of this brake.

The pitch of the helical faces is determined by the following formula :—

$$T = \frac{PL}{R \times \mu \times N}, \quad \text{and} \quad \frac{PL}{Tr} = f = \tan A ;$$

therefore,

$$\text{lead of helix} = \tan A \times 2\pi r ;$$

where,

R = average radius of disc ;
PL = torque on driving wheel ;
A = angle of helix ;
N = number of rubbing surfaces ;
μ = coefficient of friction = ·07 ;
r = mean radius of helical faces ;
T = thrust or pressure on discs ;
f = coefficient of friction of helical faces.

The brake should be proportioned so that an angle of helix of about 10° will give the requisite pressure. The brake should run at a speed not exceeding 150 revs. per minute, and the pressure on the discs should not be more than 200 lbs. per sq. in. and on the helical faces 500 lbs. per sq. in.

Manual brakes are usually of the band or post type. Band brakes should have a bar fitted round the outside of the strap with adjusting screws to ensure that when the brake is released the strap will come away evenly from the sheave.

Band brakes are generally only suitable for a torque in one direction, i.e. away from the fixed end of the strap.

To find the pull to be applied to the loose end of the strap, the following formula may be used :—

$$P = \frac{F}{e^{\mu\theta} - 1},$$

where,

P = pull ;
F = turning force on rim of brake sheave ;
e = base of Napierian logs. ;
μ = coefficient of friction ;
θ = angle of sheave embraced by strap in radians.

Brake sheaves are usually made of cast iron, but steel may be used for severe duty. The brake shoes or strap may be lined with wood, leather, or one of the asbestos fabrics such as Ferodo ; wood and leather are inclined to char and glaze and the coefficient of friction is reduced. Ferodo bonded asbestos (page 825) is not subject to these objections and maintains a constant coefficient of friction, which in practice may be taken as ·3.

Electric cranes may be controlled by dynamic or rheostatic braking if direct current is used. Dynamic braking with potentiometer control is to be preferred to plain rheostatic braking, as practically automatic speed control is obtained in the lowering direction irrespective of the weight of the load. Heavy rushes of current and mechanical shock can be produced on the motor by either systems of electric braking, and some form of current limit control should be provided.

To control the lowering of heavy loads at slow speeds, some form of hydraulic brake is the most efficient. In principle this consists of either a reciprocating or rotary pump with closed circuit and throttle valve.

The pump is in the train of gearing between the motor and the rope drum, and by means of a free wheel drive is inoperative in the hoisting direction. On lowering, the solenoid or other brake is released, and the descending load drives the gearing and pump. The speed is controlled by the throttle valve, and very fine regulation at constant speed can be obtained. Ths system is especially suitable for placing guns, turbines, and engines on board ship.

For gun tempering, armour treatment, and processes where immersion in a cooling bath is necessary, it is essential that the load should be rapidly lowered at speeds varying from 60 ft. to 150 ft. per min.

The lifting speed is about one-tenth of these speeds, and the usual practice is to disconnect the rope drum from the gearing and motor when lowering.

A coil clutch is used for the purpose, and a powerful brake must be fitted to control the lowering speed and sustain the load. Manual brakes have proved satisfactory for this purpose, particularly in conjunction with a centrifugal brake for speed control. On cranes of over 100 tons capacity elaborate electro-hydraulic systems have been used with great success, but they are very costly.

Electrical Equipment.

Cranes may be worked by either direct or alternating current, but the former is to be preferred for the following reasons :—

1. Series wound motors may be used with high starting torque and speed variation in proportion to load.
2. Very fine control can be obtained and dynamic braking used.
3. Lower first cost and less wiring.

Alternating current motors usually require less attention than direct current motors, but the starting torque is limited and the running speed is practically the same under light and full load conditions. The starting torque for alternating current motors should be not less than two-and-a-half times the full load torque, and in fixing the horse-power it is advisable to make it about 10 per cent. higher than for direct current motors for the same duty.

Squirrel cage motors are not suitable for crane work.

All motors should preferably be of the totally enclosed type. For ordinary engineering shop service crane motors rated to develop their full power for a period of half-an-hour with a temperature rise of 90° F. are quite suitable. For steel works and other situations where the duty is severe, the rating should be for one hour. It is desirable to have the yoke and bearings made in halves so that easy access may be had to the interior of the motor.

Controllers.

For ordinary crane service and motors up to about 60 h.p. the drum controller gives very good service. There should be ample room inside the controller for connections, all parts accessible, finger tips and drum contacts easily renewable, insulation of mica or micanite, and a definite step should be felt as the barrel is moved round to each contact. Magnetic blow-out should be fitted on direct current controllers.

For frequent operation and large currents a solenoid operated or contactor controller should be fitted. The contactor switches handle the main current to the motor and are controlled by a small drum, or master controller, which deals only with the shunt current required to excite the contactor coils. A development of this system is the Holme Portable Remote Control in which the master controller can be carried about by the operator and connection is made to the contactor panel by a multicore flexible cable.

Creeping control for foundry or riveting work is obtained by inserting resistance in parallel with the motor armature circuit, thus magnifying the strength of the field and enabling full load torque to be obtained at a very slow speed.

On alternating current circuits speed regulation is obtained by resistance in the rotor circuit, but the same range of speeds cannot be obtained as with direct current, particularly on light loads.

When creeping speeds are required the most practical method is to load up the motor with a manual brake, and then use the controller and resistance to adjust the speed.

Resistances.

Resistances are preferably of cast alloy or stamped steel grids assembled to prevent vibration and shorts due to distortion through heating. They may be rated to be in circuit for two or five minutes out of every fifteen minutes with a temperature rise not exceeding 350° to 400° F. For creeping control continuously rated resistances are desirable.

Switchboards.

Many cranes are fitted with a main switch and fuses for the protection of each motor circuit, but it is desirable that these should be replaced by a main automatic circuit breaker and relay switches for each branch circuit. The relay switches do away entirely with fuses and obviate the loss of valuable time at critical moments due to replacing them. Each switchboard should have a pilot lamp and socket for portable lamp connection. It is advisable, although not essential, to fit an ammeter and voltmeter.

Limit Switches.

Limit switches to prevent overwinding or overtravelling should be of the shunt type, and connected in the no-volt coil circuit of the main breaker on the switch-board, so that in the event of the switch coming into operation the main circuit is opened at the breaker.

Special contacts can be fitted on the controller to short circuit the limit switch on bringing the controller on to the first notch in the reverse direction. The breaker can then be reset and the motor reversed. The limit switch should be of the totally enclosed self-resetting type.

Solenoids.

Solenoids for brake operation are preferably of the series type on direct current circuits, but where rheostatic braking is used they must be of the shunt type, in which case a discharge resistance should be fitted to take up the induced current on breaking circuit. For alternating circuits solenoids are preferably connected in all phases. The rating of a solenoid should be the same as the motor with which it is in circuit. The coils should be enclosed as a protection against damage, dirt, and damp.

Wiring.

For crane work the current density may be in excess of ordinary practice for shop motors owing to the intermittent service, and the I.E.E. have drawn up a set of rules for this duty.

Cables, unless lead covered and armoured, should be enclosed in metal conduit. Current is supplied to travelling cranes from bare conductors stretched along the track by means of slipper or trolley collectors. The bare conductors may be of copper wire, or, as is now common practice in steel works, steel tee or angle bars ground on the sliding face.

For jib cranes the conductors may be carried overhead or in a conduit. An alternative system is to run the cables in a closed conduit with junction boxes at intervals from which connection can be made by plug and flexible cable. A drum should be fitted on the crane to coil up the slack cable.

Electro-Lifting Magnets.

Electro-lifting magnets are largely used in connection with cranes for handling all classes of iron and steel materials, and their application shows a considerable saving in time and cost compared with manual labour or even ordinary crane service with slings.

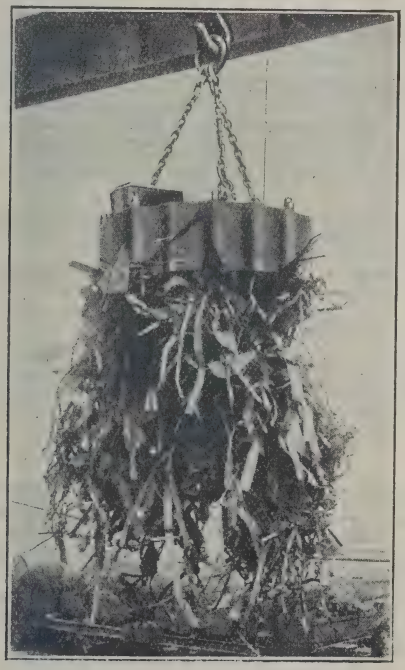

Fig. 12.

For lifting pig iron, small and heavy scrap, and large solid masses, a single circular magnet (fig. 12) is adopted, and for lifting long and wide plates two or more of these magnets are used spaced along a beam which can be slung from the crane hook.

For rails and long bars or tubes a series of two or three rectangular or oval magnets on a beam are better, as greater lifting capacity is obtained with less dead weight.

The circular type of magnet consists of an outer casing or yoke of high permeability steel with a central boss which forms the inner pole of the magnet, the walls of the casing forming the outer pole. The annular space between the poles serves to contain a coil of high conductivity

insulated copper wire or strip, secured in place and protected by a non-magnetic manganese steel bumping plate, the latter being held in position by the inner and outer pole shoes which are bolted to the casing and form the contact face of the magnet. In the 'Phœnix' magnet there are two annular recesses each with a coil; this construction increases the area of the central pole and adds to the lifting power of the magnet.

The outer casing is provided with lugs for attaching the sling chains, and a terminal box is fitted for making connection between the magnet coil and the supply cable.

The insulation of the coil is a most important detail, and it is usual to dry this in place in a vacuum and then impregnate under pressure with a special insulating compound which sets solid and renders the coil impervious to atmospheric conditions and to water.

The magnets are energised by the medium of a drum controller which switches on the current through a series resistance and has also a discharge resistance to take up the back E.M.F. when switching off.

To ensure immediate release of materials which might cling to the magnet face by residual magnetism, a reverse step for demagnetising is provided on the controller.

Messrs. Steel, Peach & Tozer have developed a special safety device to hold the load in the event of the main current supply failing. This device consists of one set of accumulators connected up to two automatic switches carried on the top of the magnet frame in such a manner that should anything go wrong with the main current the accumulators are instantly and automatically connected across the magnet winding, providing a current sufficiently strong to enable the magnet to retain its hold on the already magnetised load. There is a special switch which enables the crane driver to put the accumulators on charge each time the magnet makes a lift, and to disconnect the same when it is necessary for the magnet to release its hold. It is impossible for the accumulators to come into operation across the magnet so long as there is the main current on the magnet feeding wires, and the magnet can only be made to loose the load at the will of the crane driver.

Magnets may be used on steam cranes by installing a steam-driven generator to supply current, and this should preferably consist of a turbine set which occupies little floor space and can be fitted to almost any existing crane.

Magnets are only suitable for use with direct current; so that, where alternating current is the main supply, it is necessary to have a motor generator to convert to direct current.

It is desirable not to use a higher voltage than 220, although the 'Phœnix' magnets are now successfully installed on a 500-volt circuit.

Current is conveyed to the magnets by means of a twin flexible cable which has to be coiled up or paid out to correspond with the lifting or lowering of the crane hook. This is accomplished by means of a drum carried on the crane and either geared to the main winding drum or actuated by means of an internal torsion spring. Slip rings and brushes are provided on the drum to pass current from the fixed to the revolving parts.

TABLE OF PARTICULARS OF 'PHŒNIX' CIRCULAR MAGNETS.

Shafting, bars, billets and rails lifted . . . .cwts.	50–100	60–140	80–140	100–180	100–200	100–300	200–400
Pig iron lifted . . . .cwts.	—	6–8	7–15	9–18	11–20	15–30	18–35
Scrap iron (broken castings), heavy steel scrap lifted .cwts.	—	10–20	20–40	20–70	30–100	30–140	30–200
Scrap sheet iron, stampings, bolts, filings, heavy turnings, etc., lifted . . .cwts.	—	5–10	8–12	8–15	10–17	10–25	15–30

An important advantage with the use of magnets is the amount of floor space saved, as the height of stacking is only limited by the height of lift of the crane, and when handling billets and blooms these can be stacked close together as no space is required for the use of dogs or slings.

The following typical cases are given to show the advantages accruing from the use of magnets:—

1. 62-in. diameter circular Phœnix magnet, fitted on a 12-ton electric overhead crane, commanding a scrap storage ground. Weight of magnet about 65 cwts. Current consumption about 50 amperes at 220 volts.

2. A truck load of steel turnings unloaded in seven minutes, work which formerly took four men five hours.

3. Four large furnace boxes, each measuring 6 ft. by 2 ft. 7 ins. by 1 ft. 6 ins. deep, placed side by side on a rail lorry, filled in four lifts averaging 17½ cwts: each.

4. Four furnace boxes of the same size filled with 2½ tons of tube scrap in three lifts.

5. 52-in. diameter circular Phœnix magnet, handling steel turnings from stock heaps into railway trucks. Approximate weight of magnet 50 cwts. Approximate current consumption 40 amperes at 220 volts. The magnet made twelve lifts in seven minutes and handled in this time 95½ cwts.—an average of, say, 8 cwts. per lift. Steel turnings are difficult to handle, particularly if rusted together or with long turnings interlaced.

A 52-in. Phœnix magnet has also unloaded from trucks 600 tons of pig iron in 8¾ hours with the crane driver solely controlling the operations, no other labour being employed.

6. A pair of oval-shaped Phœnix magnets for handling combs of pigs. Without the magnets the time occupied to lift a bed of 22 combs was four hours; with one set of magnets the work is done in sixteen minutes.

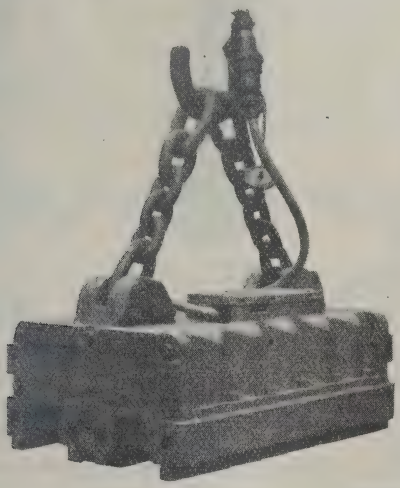
With the magnets in use, only two or three ground men are employed, whereas hitherto 30 or 40 were required.

Steel may be handled by magnets up to a temperature of about 700° C.

Fig. 12 shows a 52-in. diameter steel magnet handling scrap.

Mobile Finger Magnet.

For lifting rails and bars of similar section, Messrs. Allen West & Co., Ltd., have developed a rectangular magnet (fig. 13) along the face of which are four rows of short steel pieces free



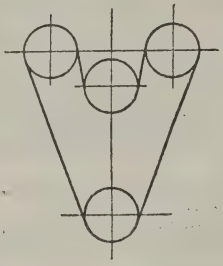


Fig. 13.

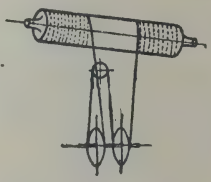

to move and adjust themselves to the contour of the bar to be lifted. Owing to these steel pieces forming a better path for the magnetic lines of force, the lifting capacity of the magnet is increased when dealing with irregular sections.

Durability of Wire Ropes.

The two most important conditions appertaining to the manufacture and use of steel wire ropes that affect their durability are:

(a) Quality of material and size of wire.

(b) Diameter of pulleys and arrangement of ropes.

(a) Wire used for lifting ropes is of steel whose ultimate tensile strength varies from 80 to 130 tons per square inch. Ropes of material having a higher tensile strength are of smaller diameter for a given load and factor of safety, but since they are stiffer, larger drums are necessary to obtain the same durability.

The stress in a wire due to bending round a pulley is proportional to:

$$\frac{\text{(Modulus of elasticity)} \times \text{(Diameter of wire)}}{\text{(Diameter of pulley)}}$$

hence large wires are more quickly fatigued than small ones. On the other hand, small wires are more quickly worn through.

For a given ratio of pulley to rope diameter, given rope diameter and load, the life of the rope, if limited by abrasion and not by fatigue, increases as the square of the diameter of the wires of which it is made.

(b) For a given diameter of rope (d), diameter of wire (a) and load (P), the life of the rope depends on the square of the ratio of pulley to rope diameter (m) for large values of the latter.

The above statements have also been deduced from theoretical considerations by Prof. J. T. Nicolson, D.Sc., and may be represented by the formula given by him.

$$\text{Life of rope} = C\frac{m\,(m+1)\,d^2a^2}{P}$$

where the symbols m, d and a have the meanings given above, and C is a constant.

The practice of passing wire ropes on a crab as shown by fig. 14, entailing successively a 90° bend, a 180° reverse bend, and a 90° bend, is a bad one and deteriorates the strand wires:

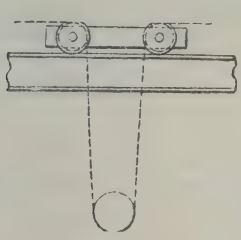

Fig. 14.

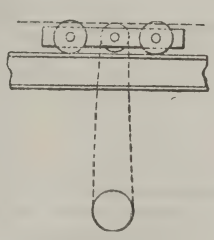

Fig. 15.

a better method is shown by fig. 15, the rope being taken over one upper pulley, down to the block, and up over the second pulley, the bend being always in the same direction, the reverse bend being thus abolished; this arrangement will increase the life of a rope as much as 50 per cent.

The effect of different arrangements of pulleys is shown by Nos. 1 to 7, page 802, and the accompanying tables, case No. 1 being taken as the standard.

† Points to remember in connection with wire ropes :

1. In general, use the lowest grade of steel.
2. In general, use the middle flexibility.
3. Use Lang's lay, if possible.
4. Ratio of pulley to rope diameter should not be less than 26 ; 30 is better.
5. If possible, employ a ratio of pulley to rope diameter of 40, and then keep to the lowest instead of the middle flexibility.
6. In the case of peculiar double turns, use pulleys as large as possible.
7. Avoid unnecessary reverse bends.
8. Keep the ropes well oiled.

* Including one reverse bend which is twice as effective in wearing out the rope.
† Mr. George Hughes, M.I.Mech.E., in Proc. Inst. Mech. Engrs. 1912.

The makers also supply ropes in the construction of six strands each containing 61 wires per strand, from 2½ ins. circumference and upwards; also ropes of six strands each containing 91 wires per strand, from 3 ins. and upwards. The breaking stresses for both these constructions are somewhat lower than those given in the above table for six strands each containing 37 wires per strand. Ropes of other constructions, and *of any size*, are also made for crane work by Messrs. T. & W. Smith, who will furnish full particulars on application.

ELECTRIC LIFTS.

Typical Specification for Electric Lift.

The following are the main particulars of the lift :—

Extreme travel . . 38 ft. 9 ins. Speed . . . . 120 ft. per min.
Maximum load to be carried 10 cwt. Inside dimensions of cage 3 ft. 6 ins. × 3 ft. × 7 ft. high.

Position for Motor, etc.—The motor, etc., to be placed in the basement in the position shown in the plan.

If fixed overhead, the driving sheave or drum should be designed, if possible, to span correctly from the centre of cage to centre of weight, so as to save the use of diverting sheaves.

The overhead sheaves are to be supported on suitable rolled steel joists, to be supplied and put in position by the contractor.

Cage.—The cage walls are to be made of well-seasoned pine, with a substantial iron or steel framework, and adjustable guides at the top and bottom to work on the runners. No seat will be required. A Bostwick or other approved sliding gate to be provided at the cage entrance.

The construction of the cage may be either (*a*) framed with grooved and tongued panels, the woodwork forming the panels being put in diagonally, and the whole bolted to the iron framework of the cage ; or (*b*) of grooved and tongued planks on the flat bolted to the iron framework of the cage with an additional strengthening iron ; or (*c*) of an approved type. If method (*a*) is adopted, the framing must not be of less than 1½ in. stuff, and the panels not less than ¾ in. ; if (*b*) the planks must be uniformly 1 in. thick. The floor of the cage must be of maple, 2 ins. thick. All the above dimensions are finished sizes.

An opening to be provided in the top to allow for the lighting of the cage by daylight. This opening is to be covered over and under with iron wire trellis of 1 in. mesh, of not less than No. 13 S.W.G. The wirework to be galvanised after it is made up.

The interior of the cage, with the exception of the floor, to be varnished with three coats of good oak varnish.

The cage to be fitted with an electric light fitting of the bulkhead or other approved type, with genuine enamel reflector. A bayonet collar lamp-holder, lamp, cut-out and tumbler switch for this fitting, and a length of flexible cable for making connection to a ceiling rose fixed about half-way down the lift-well, to be provided and fixed by the contractor.

Electric Bell.—Suitable bell pushes are to be provided and fixed on each landing, and connected to an electric bell, to be provided and fixed in and about midway up the lift-well, and to an indicator for each floor, to be provided and fixed in the lift cage. A battery for working the bell is to be provided.

The whole of the bell work, including the necessary wiring, is to be done in the most approved manner.

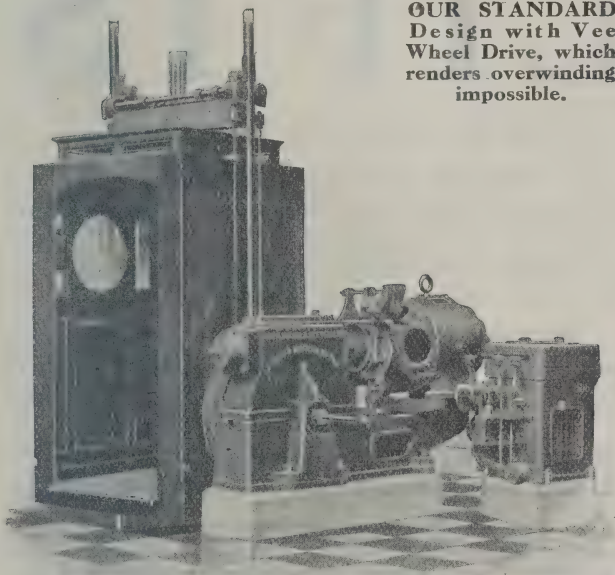
Gates for Cage and Openings in Lift Well.—Collapsible gates, with spring-catch lock of the Bostwick, B. and S., or other approved pattern, are to be provided and fixed to the lift-well openings on each floor, to the lift cage and motor enclosure. Six gates in all will be required. The locks and gates (except in the case where push buttons are required to be fitted) to be so constructed that they cannot be opened except by use of the authorised key.

The gates, which are to be carefully finished black, are required to open the width of the cag opening, and to reach to the top of the cage opening.

Lift-Well Enclosure and Wirework Guards.—A wirework guard is to be fixed to the gate uprights, and continued round the lift-well above and below the hand-rail from the basement to the second floor at a height of 7 ft. from the stair treads. Suitable supports for the attachment of the wire guard are to be provided, and care is to be taken to prevent the guard or its supports from interfering with the free use of the stairs hand-rail. The guard is to be over and under iron trellis of 1 in. mesh, not less than No. 13 S.W.G., and is to be finished black, and stiffened where necessary by angle iron or tubing.

A wirework screen with suitable channel iron supporting frame, at least 7 ft. high, with Bostwick gate, to be provided in the basement for the protection of the motor and gear.

*Carrying Capacity and Speed.**—The cage to carry a maximum load of 10 cwt., and to travel at a speed of 120 ft. per minute when fully loaded. The maximum variation of speed ascending or descending at any other load must not exceed 10 per cent.



---

* In the case of passenger lift with car switch operation, the speed is now from 200 to 300 feet per minute.

ELECTRIC LIFTS

FOR ALL PURPOSES.

Embracing all essential Factors for
RELIABILITY, SIMPLICITY AND ECONOMY.
BRITISH MANUFACTURE THROUGHOUT.

OUR STANDARD Design with Vee Wheel Drive, which renders overwinding impossible.

Combination for Passenger Lift with Electric Control from Cage.

Cage Guides.—The guides are to be of round turned steel, or machined steel tees, without backings in either case. They must be sufficiently strong and securely attached to the sides of the lift-well to withstand any stress to which they may be subjected, due to the action of the cage safety gear.

Motor.—The motor is to be either of the iron-clad or of the protected type, with commutator and brushes enclosed. It is to be wound for 200 volts continuous current, and its speed is not to exceed 850 revolutions per minute. It is to run absolutely sparkless and silent under all conditions of load.

The rating of the motor will be based on a six hours' intermittent test, half an hour run under maximum lift duty, followed by half-hour's rest, with an overload capacity of 50 per cent. for short periods, without the temperature rising more than 70° above surrounding atmosphere. The motor will be coupled direct, by means of coupling to the worm shaft of the gearing. The journals of the motor will revolve in phosphor bronze bushes, with specially constructed lubricating rings, and oil chambers of ample capacity.

Gearing.—The power will be transmitted from electric motor to the winding sheave by means of a specially constructed worm and worm wheel gear. The worm wheel will have an ample bearing surface and be either of hard cast iron with teeth cut from the solid, or with a cast-iron centre and rim and with teeth of phosphor bronze. The worm will be of good quality mild steel bar or forging, with the thread cut from the solid to suit the wheel. The whole gear will be enclosed in a cast-iron case, and be partly submerged in oil, so as to ensure an ample supply of lubrication and to exclude dirt. The thrust of the worm shaft will be taken by a special thrust bearing of approved design and arranged for easy access for adjustment or repair. The shaft of the worm wheel will carry a specially constructed cast-iron V-grooved wheel, turned and grooved to receive the wire ropes and with suitable bearing for outer end of shaft. The motor will be fixed on a cast-iron bed plate, which carries the worm gearing, for rigidity. The efficiency must be such that the gearing is self-sustaining when at rest.

Brake.—The brake will act upon the motor shaft, and will be of the electro-mechanical type, and will always be in action excepting when the motor is revolving, and will be so arranged as to arrest the motion of the machine in the event of interruption of the electric circuit from any cause.

Method of Control and Switch Gear.—The lift is to be controlled from the cage by means of a hand-switch capable of starting, stopping, or reversing the motor. The cage switch is to be self-restoring to the 'off' position when released. The switch-gear is to be so arranged that the lift cage starts smoothly and independently of the rate at which the hand-switch is operated. It must also be impossible to stop the cage with a sudden jerk by means of the controlling switch.

There must be no undue sparking at the contacts of either the cage-switch or switch gear' and they must be generally so designed that they can be left for long periods without attention. All switches and connections are to be designed to carry without appreciable heating, and all resistances without excessive heating, double the maximum current which will at any time under working conditions pass through them. All wearing parts to be easily and cheaply renewable.

The working of the lift (subject to the conditions of the power supply) is not to cause any appreciable fluctuations to the voltage of the lighting circuit, the starting current required for the motor being put on gradually by steps (not including the step from zero) not exceeding 10 amperes, and not at any time exceeding 1½ times the rated full load current of the motor.

Main Switch.—A main double-pole switch to be provided and fixed at the point where the cables conveying the current for working the lift enter the motor enclosure at the basement level.

Leads.—The current to be conveyed to the motor enclosure by suitable vulcanised india-rubber covered cables terminated at the main switch before described. All connections required from this switch are to be provided and fixed by the contractor. The cable used for connections is to comply with the specification for vulcanised india-rubber covered electric light cable, and may be of the 'medium insulation' quality but with braided mechanical protection. All wires and cables supplied and fixed by the contractor are to be heavily braided and protected by being enclosed in W.I. barrel. The W.I. barrel to be efficiently connected to 'earth.'

Sizes of Conductors.—The conducting leads provided by the contractor are to be in accordance with the Institution of Electrical Engineers' Table, taking the full working load as the basis. Terminals, switches, connections, etc., whether of copper or other metal, are to be of such sectional area that their conductivity shall not be less than that of copper based on a maximum current density of 500 amperes per square inch.

Insulation.—All electrical parts must be well and satisfactorily insulated, and the actual insulation of the finished installation measured from the terminals of the main switch must not be less than one megohm, either between the positive and negative terminals with either pole of the motor disconnected or between both terminals and earth with all intermediate switches closed.

Safety Devices.—The most improved system of safety devices is required. A full description of all safety devices to be employed is to accompany tender. They must include the following :—(*a*) The locking of the cage on the guides or guide backings if one or more of the suspending ropes break or slacken ; (*b*) automatic stopping of the motor when the cage is brought to rest from any cause, unless the V wheel drive is used ; (*c*) automatic stopping of the cage before it reaches the top or bottom of the lift well.

Painting.—The whole of the materials fixed and supplied by the contractor, with the exception of the electric light and bell fittings, cables and resistances, bright metal work, folding gates, and the inside of the cage, which is to be varnished, is to be painted with three coats of oil paint, the finishing coat to be of a colour to be selected. The wood work, including all portions of the cage which are not visible, is to be knotted and primed before being painted.

Lubrication and Contact Cleaning.—The whole of the plant is required to work automatically and to require no attention beyond occasional lubrication, and occasional cleaning of the contacts.

Factor of Safety.—The factor of safety for the suspending ropes is to be not less than ten, and for all other parts a factor of safety of at least five is to be provided.

Precautions against Fire.—The contractor is required to make such arrangements as will prevent an outbreak of fire should the armature or any other part of the apparatus fuse or become excessively hot.

Quality of Material.—The material and workmanship to be of the best possible description throughout.

Tests.—Immediately the lift has been erected, the contractor will be required to make the following tests to the satisfaction of the inspecting officer :—

1. The cage to be loaded until the weight on the ropes is twice the combined weight of the cage and specified maximum load. The gear and suspending ropes must bear this weight for 30 minutes without showing any sign of weakness, temporary set, or permanent elongation of the rope strands.

2. Tests to determine if the specified speed is complied with.

3. Tests to determine if the various safety devices comply with the conditions of the contract.

These are to include : (*a*) Starting the cage up and down and letting it run to the end of its journey without attention ; (*b*) slackening one or more as required of the suspending ropes.

4. Tests to determine the suitability of the switching gear.

The contractor is required to provide a man to start the lift and to attend to it for one week from the time when it is accepted as running satisfactorily.

Leading makers such as Messrs. *Smith, Major & Stevens, Ltd.*, and Messrs. *Waygood-Otis, Ltd.*, use the following speeds on their lift motors, for continuous current :—

Up to 3 h.p. . . .	1,000 revs.	Up to 7½–10 h.p. . .	650–750 revs.
„ 5 „ . . .	930 „	„ 15 „ . . .	500–700 „

For single phase, 50 periods, 6 pole machines usually.

For 2 and 3 phase, 50 periods, 6 pole up to 10 h.p., and 8 pole above.

ELECTRIC WINDING.

The Ward Leonard System.

This system (fig. 16) is based on the fact that the speed of a separately excited D.C. motor is directly proportional to the voltage applied to the armature. If, therefore, the D.C. motor, 1, is used to drive the drum D, it can be made to run at any desired speed and in either direction of rotation, by varying the voltage and direction of the current impressed on the armature. This D.C. power is obtained from a separate generator, 2, known as the variable voltage generator, and driven at constant speed by a motor, 3, connected to the supply mains. The variable voltage generator and its driving motor are coupled together and mounted on a common bedplate, which also carries, on the same shaft as the other two machines, a small D.C. generator. This generator supplies the excitation current to the variable voltage generator and the winding motor, the triple combination being known as the converter set.

A regulator, 5, is used to vary the field of the V.V. generator and, consequently, its voltage between 0 and a ± maximum, and in this way the speed of the winding motor to which this voltage is applied can also be varied between zero and ± maximum.

The principal feature of the control is that the speed and direction of rotation of the winding motor are determined solely by the regulator or, in other words, by the position of the driver's control lever. For all practical purposes this holds true whatever the load in the cage may be, and whether the load is being raised or lowered. When in a running position—by moving the control lever towards the 'off' position—a strong electrical braking effect is obtained, as the motor then acts as a generator and returns energy through the converter set to the line. The same electrical braking effect can be obtained when lowering loads, and the low speeds required for inspection tests can be readily obtained by a slight movement of the lever from the 'off' position.

It should be noted that the controller only deals with the field of the V.V. generator (about 2 to 3 per cent. of the output), consequently, it is very small as compared with an A.C. controller, and can be readily operated even on the largest winders without the use of auxiliary gear.

As any given position of the control lever corresponds to one speed only, and one direction of rotation, it is possible to provide simple safety appliances of absolute reliability.

In Fig. 16 is shown diagrammatically the Siemens system for the automatic control of the acceleration and retardation.

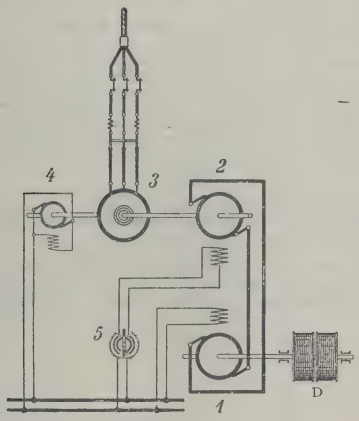

FIG. 16.

1. Operating Lever. 2. Controller. 3. Control Cam. 4. Depth Indicator.

The spindle of the depth indicator drives two cam wheels, one for each cage, through gearing proportioned so that the wheels make nearly one complete revolution. Each wheel has two cams, one for acceleration and one for deceleration. When starting, the control lever can only be moved from its mid position at a rate determined by the shape of the cams, which shape is designed to give the predetermined rate of acceleration. This rate cannot be exceeded. When retardation should begin, if the driver has not already started to bring back his lever, the deceleration cam gradually forces the lever back to the 'off' position. Acceleration, retardation, and speed of wind are thus within the driver's control, provided he does not attempt to exceed the limits for which the cams are designed.

In the event of an overspeed, electric braking automatically takes place. The winding motor will act as a generator and supply power to the V.V. generator, which will then act as a motor driving the set above synchronous speed, causing the induction motor to act as an asynchronous generator and pay back power to the line. Should the speed of the set exceed a predetermined maximum, a centrifugal switch driven from the shaft of the set will open the circuit of the brake magnet and apply the emergency brake.

AERIAL ROPEWAYS.

Aerial Ropeways may be divided into two fundamental types:—The SINGLE ROPE or MONOCABLE, and the DOUBLE ROPE or BI-CABLE. In the first, a single endless rope is used both to support and move the loads. In the second, there are one or more supporting ropes and an endless hauling rope. Adopted to these types are the 'Fixed or Non-detachable Clip System,' on the Single Rope Type, and the 'Jig-back' or 'To-and-fro System,' which is applicable to either type.

There is considerable divergence of opinion upon the merits and demerits of the two systems, which is due largely to the fact that a number of plants have been installed without giving due consideration to which type is most applicable to the nature of ground to be traversed, and the duty to be performed.

THE SINGLE ROPE OR MONOCABLE SYSTEM.

Ropes.

By experience, it has been found the most suitable form of rope on an average length line is a 6·7 Lang's lay, with a specially hard hemp core. On short lines when the rope is subject to a great number of bends per hour around the terminal sheaves, compound lays are sometimes used. Wire cored ropes are also occasionally employed, owing to the fact that they tend to stretch less than those with hemp cores, but they have been found by experience not to have such a long life.

On a well-constructed line, depreciation on rope is covered by ·125 pence to ·3 pence per ton mile carried, on the basis of a line not less than 1,000 yards long, and a capacity of over 25 tons per hour; as the length and capacity increases, the depreciation per ton mile carried decreases. The fact that on a single rope system the entire length of the rope is constantly passing under observation at the terminals renders it very safe against failure, and it can be worked until a comparatively low factor of safety is reached. The diameter and breaking strain of ropes can be obtained from the formula given on page 804, under 'Diameter of Hauling Ropes.' No rule can be given, however, for finding initial tension, as this is dependent upon driving power required and spans to be negotiated, etc., apart from capacity of line and so forth.

Loads.

When possible, individual loads should be kept to about 1 per cent. of the hourly capacity of a line, for the purpose of distributing the weight on spans. Heavy individual loads tend to increase prime costs.

Carriers and Clips.

Among the best known are Roe's Patent Toggle and Saddle Clips.

The former, fig. 17, is capable of sustaining a load at an angle of over 45°, and in theory is the most efficient of all clips actuated by the load, as the whole of the tare weight also is used

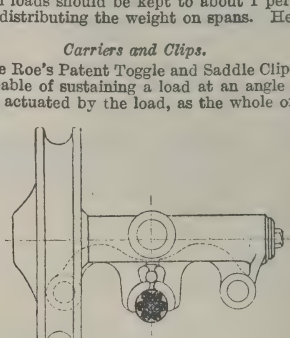

FIG. 17.

for gripping. In practice, however, the saddle clip, fig. 18, is found preferable and is usually adopted. The gripping in this type is performed by two cast chilled saddles, the sides of which are inclined, one side having a feather projection which engages into the lay of the rope, this projection being so formed that it disengages itself without damaging the strands when the carrier enters a station. The ruling grade on which this type of clip can be safely worked is 1 in 2¼. The tare weight of clip, carrier, and bucket is usually about one-third of the net load.

Fig. 19 shows the 'Roe Balance Beam.' The arrangement is used for distributing the pressure equally on a series of sheaves; these are arranged in groups of 2, 4, and 8. The introduction of a number of balanced sheaves in series greatly facilitates the working of long spans, and reduces wear and tear of rope where heavy pressure on any trestle has to be sustained.

A fair speed for the rope is 400 ft. per minute, though under certain conditions it can be run up to 550 ft. per minute, when no automatic return or dumping is required. The factor that rules the speed is the velocity at which the loads can be brought up to for engaging

with the rope, bearing in mind that the load and rope velocity should synchronise at the point of attachment.

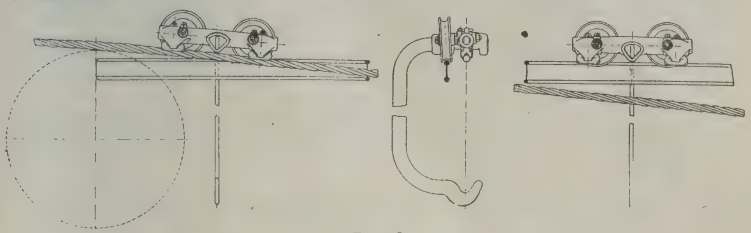

FIG 18.

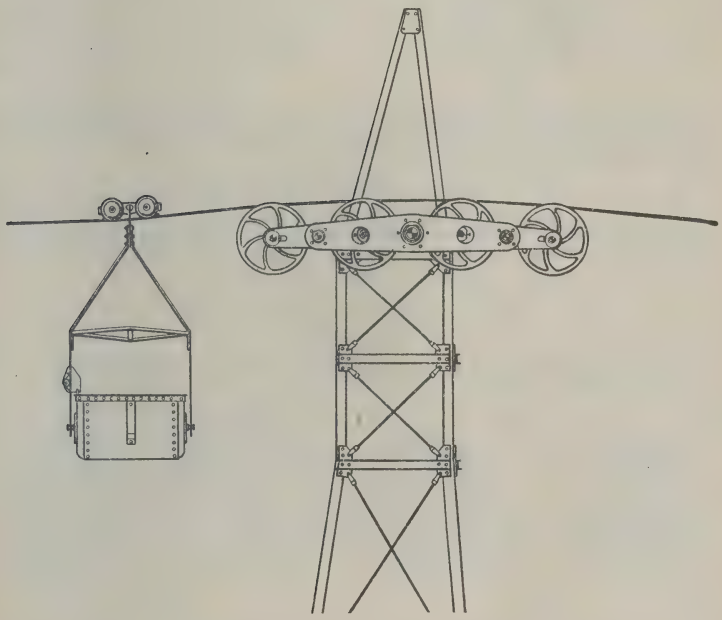

FIG. 19.

Power.

Any available power can be used as long as it is steady. Trouble, however, may be caused by using intermittent power, as this gives rise to oscillation of the rope in long spans. On automatic lines, the surplus power is preferably absorbed by means of a fan or turbine. When possible, the power should be placed at the upper end of a line, and the tension at the lower terminal. In long lines that have to be sectionalised, the driving or brake station, as the case may be, is sometimes placed between two sections, and the tension arrangements at the ends.

Tension.

To insure a constant and even tension, it is essential that the counterweights should be always free and floating, and owing to the amount of stretch in hemp cored ropes, taking-up gear must also be allowed for. Fig. 20 shows an arrangement which combines a multiplying and taking-up device. The two sheaves at A are attached to the tension trolley, the winch and differential drum being mounted on an independent frame placed over the tension

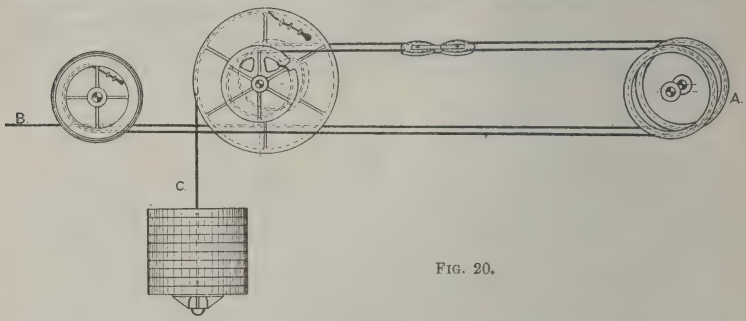

FIG. 20.

pit: one end of the rope B is anchored, the other being made fast to the tension winch drum. By this arrangement the resultant pull at A is four times the dead weight applied at C, and the weights can always be kept in suspension without the necessity of a deep pit, by taking in the slack with the winch.

Spans.

The distance between standards is dependent on the configuration of the ground, but over undulating country the average distance is approximately 330 ft. for lines of up to an hourly capacity of 60 tons. On a ropeway over the Andes, having a total length of 46 miles, several spans are being worked of 2,800 ft., though the longest recorded span on the single rope system is 3,600 ft.

BI-CABLE SYSTEM.*

Carrying Ropes.

Carrying ropes may be divided into two main classes, 'spiral,' fig. 21, and 'locked coil,' fig. 22. The main advantage of the spiral type is its cheapness, and in lines transporting a small tonnage

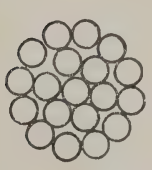

FIG. 21.

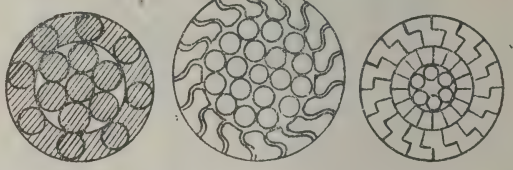

FIG. 22.

per hour it will generally answer its purpose. Ropes of this type should consist of 19 wires in ropes up to 1 in. diameter and of 37 wires in ropes up to 1½ in. diameter. With this latter the individual wires have a diameter of about ·205 in., which is about the limit to ensure perfect homogeneity of the material. Above 1½ in. diameter, locked coil ropes should invariably be used.

Locked coil ropes, fig. 22, are of two types, the special locked, *a*, and the full locked, *b* and *c*. The former consists of a spiral core surrounded by a layer of round wires kept apart by wires

* Abstract, by permission, from 'The Engineer,' July 23 1915.

drawn to a special section. This rope is sold at a medium price between plain spiral rope and full locked coil. The surface of the special locked rope is not perfectly smooth, small interstices occurring between the wires. The full locked coil, on the other hand, presents a perfectly cylindrical surface to the passage of the cars. The second type of full locked construction—shown at *c*—is particularly useful for very heavy carriers, as, owing to the rope having an inner layer of tapered section wires, the crushing and distorting effect of the load when passing over the saddles on which the rope is supported is minimised. In addition to the great advantage of offering a smooth surface to the wheels of the cars (with the result that the wires may be of a lower breaking stress than with spiral ropes), the locked coil ropes possess the great advantage that, should by any chance one of the individual wires break, it is held in place by the neighbouring wires, and does not spring from the texture of the rope, as is the case with the spiral construction. This springing of the wires is often the cause of accidents, as the cars run against the outstanding wire, and are thrown off the line.

Fixture of Ropes.

The ropes are anchored at one end of their length, and some form of tensioning device applied at the other end. This generally takes the form of a hanging weight, which may generally be from one-quarter to one-fifth of the total breaking strength of the rope. A factor of safety of 4·5 is a good medium. It has been proved that for spiral ropes a breaking stress of 95 tons per square inch, and for the locked coil ropes 65 tons per square inch, give the best results. When calculating the tension weight required, the fact must be taken into account, that should the weight be situated on a lower level than the anchorage, the weight of the rope itself acts as a tensioning factor.

For fixing the ends of the rope a satisfactory arrangement is to employ the ring wedge coupling. In this anchorage—shown in section in fig. 23—the single wires are kept apart by small nail-like

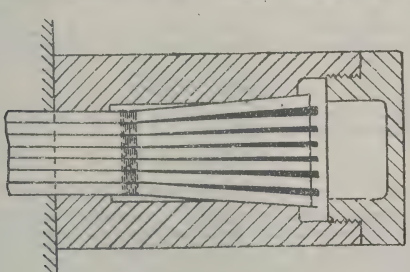

FIG. 23.

wedges, and the layers by means of ring wedges made in halves. These wedges are driven in and then a cap is screwed home, firmly locking them in place and entirely preventing any chance of the wires pulling out.

The same form of coupling, only made tapered at both ends, fig. 24, may be used for joining the various lengths of rope along the line.

FIG. 24

The distance apart of the tensioning weights varies according to the carrying capacity of the line, weight of carriers, number of long spans occurring, etc. A good rule is not to exceed a length of 1½ mile between anchorage and tensioning device, although on level lines, with a small capacity, distances up to 2 miles may be taken.

Another method of tensioning is by means of buffer springs at either end of the rope, but this system is only applicable to short lines with light loads.

Diameter of Carrying Ropes.

It has been proved by experience that most trouble is caused by breaking due to bending near the saddles, and for this reason in order to obtain the diameter of the carrying rope

required, many firms employ formulæ based on stresses due to bending. A formula often used is :—

$$\text{Weight per metre of ropes} = \frac{0{\cdot}85}{100}\left\{(\text{weight of carrier}) + \Big((\text{distance between carriers in metres}) \times (\text{weight of traction rope per metre}).\Big)\right\}$$

This is for spiral construction ropes. With locked coil ropes the factor 0·85 becomes 1·05. This works well for small lines up to about 50 tons capacity hourly. For each additional 5 tons, 0·05 should be added to the factor 0·85. The following table shows the various diameters of a special locked rope for various loads and traction ropes :—

(Two-Wheeled Carriages.)

Dia. of Hauling Rope.	Weight of Loads in Cwts.

Design of Ropeway.

To lay out the profile for a ropeway, when the line is laid out on paper, the curve of the rope may be obtained and set out from the formula—

$$\text{Dip} = L^2\ W/8\ T,$$

where,

$$L = \text{span};\ W = \text{weight per unit length};\ 8 = \text{constant};\ T = \text{tension},$$

and then the supporting trestles placed accordingly. It sometimes happens, however, in practice that when the rope is fully tensioned it 'floats' or rises up from the supporting tower, owing perhaps to a minute error in the drawn profile. To avoid this, some Continental makers employ a so-called factor of safety for the dip—that is, the denominator 8T is multiplied by a constant —the formula giving, as a result, a dip smaller than the actual. It will be obvious that if the curve with the dip so obtained is set out and the trestles drawn up to it, they will be slightly higher than need actually be the case, thus avoiding any possibility of 'floating' when the line is erected. This factor of safety may be 1·5 for spiral ropes and 1·1 for locked coil ropes.

There has been of late years an increasing tendency to employ saddles (upon which the rope is supported at the trestles) which are pivoted at the centre, and can consequently adapt themselves to the varying gradients of the rope, and there is little doubt that this type when properly designed, and well greased to allow of play in the rope, gives full satisfaction. In designing the shoes a good medium value for the pressure of the rope is 250 lbs. pressure per square inch of projected area of the rope. This is for locked coil ropes; for spiral ropes a little less should be taken.

It sometimes happens that at a trestle, on either side of which are long free spans, there is a heavy downward reaction of the hauling rope, which, when the carrier passes over the saddle, produces a heavier pressure on the rope than that for which it was calculated. In this case the rope is protected by means of a steel plate cap over which the carrier runs, thereby removing the pressure from the rope. There is a difference of opinion as to when these caps should be employed, but it may safely be said that their use is to be recommended where the hauling rope reaction exceeds 450 lbs.

Hauling Ropes.

The *traction* or *hauling rope*, by means of which the carriers are propelled, is invariably a stranded rope with a hemp core, the flexibility depending on the size of the individual wires in the strands and the breaking stress of the material. This rope is endless and in constant motion. In the general case it passes round a driving sheave at one end of the line and round a surging or tension sheave at the other end. In some cases this plan may be varied, as, for instance, when the carriers are required to pass automatically round a large sheave at one end station. In this case no manual attention is required at this station and the driving and tensioning sheaves are combined in the station at the opposite end of the line. Whenever possible

the driving should take place at the upper and the tensioning at the lower end of the line. In this way the accumulative tension in the rope due to its own weight is utilised as a tensioning agent, whereas, were the tensioning to take place at the upper end, an additional amount of weight would be required to counterbalance the weight of the rope. The amount of the tensioning weight should be such as to give sufficient grip round the driving sheave to ensure perfect driving when the full load is on the line.

Diameter of Hauling Ropes.

The diameter of the hauling rope depends upon the highest tension occurring in it

$$\text{Tension of rope in lbs.} = \left\{\text{Initial tension} + \left(\frac{W}{S} \times H\right) + (w \times H)\right\} + \left\{(W \times \mu_1 \times N) + (L \times \mu_2 \times w) + (R \times 2)\right\},$$

where,

W=weight of full carrier; S=spacing of carriers in feet; H=difference in level between stations in feet; w=weight per foot of traction rope; μ_1=coefficient of friction of cars; μ_2=coefficient of friction of traction rope; L=length of line in feet; N=number of carriers on one side of line; R=number of supporting rollers on one side of line.

This tension if multiplied by the factor of safety—6 to 8—and divided by the breaking stress, gives the area of the rope necessary. This is for the general case with the drive at the upper terminal and the loads ascending. When the loads are descending, the plus sign in the centre of the formula becomes minus. To obtain the tension when the ropeway is just put into work the second half of the formula should be doubled.

The usual breaking stresses of traction ropes are from 80 to 115 tons per square inch. The surge of the hauling rope tension sheave depends upon the distance apart of the carriers, whether long spans occur in the line, etc. As an average, 6 ft. play may be allowed for to commence with, and then an additional 12 ft. for each mile of length. In some cases in long lines it is necessary to split up the line into sections to avoid excessive tensions occurring.

Driving Power.

$$\text{Power in ft. lbs.} = \left\{\left(W_1 \times W_2 \times \mu_1 \times \frac{N}{2} \times V\right) + (w \times 2L \times \mu_2 \times V) + (2R \times V) + (F)\right\} + \text{or} - \text{theoretical power},$$

where

W_1=weight of full carrier; W_2=weight of empty carrier; μ_1=coefficient of friction for cars; N=total number of cars on line; V=velocity in feet per minute of cars; w=weight per foot of traction rope; L=length of line in feet; μ_2=coefficient of friction for traction rope; R=number of supporting pulleys; F=power required for station friction.

The first four factors give the power necessary to overcome friction, and the theoretical power required or developed depends upon whether the loads are ascending or descending. The factor for station friction varies greatly for different lines, and is solely a matter of experience, although 0·02 of the total weight of the moving parts in the stations multiplied by the speed may be taken as a good mean.

Carriers.

There are two kinds of carriers in general use, those employing screw grips and those with lever grips. These may again be divided into sections, the overtype and the undertype grips. In the former, the hauling rope is attached to the carrier or running head at a point above, and in the latter at a point below the carrying rope.

The main advantage of the overtype grip is that the length of the stations is shorter than with the undertype grip, as the hauling rope may be led in and out of the jaws without interfering with the shunt rails. In the case of lever grips the overtype is generally the cheaper, and on lines containing no steep gradients can often be employed with advantage. Further, it may be more easily adapted for taking curves in both directions than the undertype. The overtype grip has, however, several great disadvantages. Chief amongst these is the fact that when ascending steep gradients the traction rope reaction falls outside the wheel base, tending to tip the whole running head, a tendency which may not be counterbalanced by the weight of the carrier, with the consequence that the whole apparatus leaves the line. Again, owing to the fact that the centre line of the hauling rope must fall outside the centre line of the carrying rope to avoid any entangling, there is a decided tendency for the carrier to tip sideways as soon as a heavy hauling rope reaction occurs, a tendency which is very detrimental to the perfect working of the line when it is required to discharge the contents of the carrier automatically whilst the carriage is on the open track. These defects may be remedied by having the hauling rope directly below the carrying rope, i.e., using an undertype grip. Practically the only defect

of this type is that the stations are generally longer than with the overtype grip, thus involving extra structural work. Even this may be overcome by employing an undertype grip in which the jaws open downwards instead of upwards, as is usual.

The speed at which the carriers should be run depends upon whether it is necessary for them to be hauled automatically round curve or return sheaves by the traction rope. The following figures represent good practice :—

Straight lines	400–450 ft. p.m.
Curves up to about 45° change of direction	Undertype up to 400 ft. p.m. Overtype „ 300 ft. p.m.
With automatic haul-round—	
Sheave, 20 ft. dia.	Undertype, 350 ft. p.m. Overtype, 300 ft. p.m.
Sheave, 16 ft. dia.	Undertype, 300 ft. p.m. Overtype, 250 ft. p.m.
Sheave, 12 ft. dia	Undertype, 200 ft. p.m. Overtype, 150 ft. p.m.

The running wheels should be of high quality cast steel, the diameter depending on the load and type of rope, larger diameter wheels being employed with spiral ropes than with locked coil. The runner pins should be self-oiling. The following table gives some diameters of wheels for varying loads, carriers with two wheels being employed :—

Weight of load and carrier, cwts.	Diameter of wheel, ins.
14	8
30	10
40	12

Screw Grips.

There are two distinct main classes of screw grip, in the first of which the grip is operated by a lever and strikers in the stations. In the second the grip is operated by the weight of the carrier and load. The best example of the former is shown in fig. 25. There are two jaws—(*a*) the movable and (*b*) the fixed. The movable jaw is actuated by a shaft carrying two screws, one a rapid thread and the other a fine thread. This shaft is turned by the lever C. The action of the grip is as follows :—On the lever C being turned over, the rapid thread operates and the movable jaw quickly approaches the fixed jaw until the rope is just gripped. The fine thread now comes into action and applies the necessary force to grip the rope firmly. To unlock the

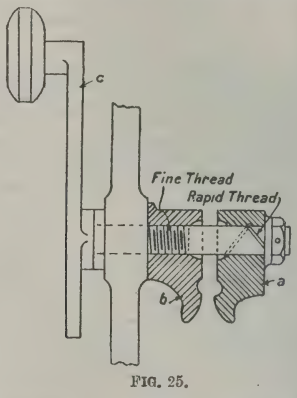

FIG. 25.

grip the reverse action takes place. The lever C is actuated at the stations by strikers constructed of angle irons.

In the other form of screw grip, in which the pressure is obtained from the weight of the carrier and load, the action is the same, the necessary turning moment being applied to the screw by hanging the carrier at the end of the lever arm. The grip is opened to allow of the rope entering or leaving, by means of rails, generally formed of angle irons, which depress small pulleys fixed at the end of the lever arm opposite to that on which the carrier is hung, thus raising the latter and thereby opening the jaws. It has been found in practice that the position of this lever arm should not be less than 35° to 40° to the vertical, to allow of easy depression of the rollers.

Lever Grips.

One of the best known Continental types is that shown in fig. 26. In this grip the pressure is applied by the weight of the carrier and load acting through a simple system of levers to give a multiplied pressure on the jaws. The grip is released by lifting the load, which is accomplished by means of small rollers running on to rails in the stations. Another type of grip—the

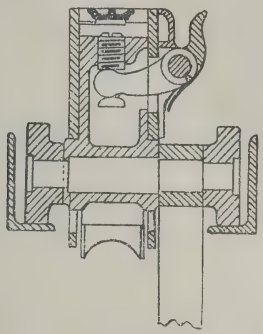

FIG. 26.

inclined plane type—is illustrated in fig. 27. The carrier and load are attached to a hanger having at its upper end a curved slot. This slot engages with a circular pin attached to the movable jaw. The downward pull of the hanger draws in this pin and with it the movable jaw, thus closing it upon the rope. When the pin is in the upper part of the slot the grip is absolutely locked, as no amount of upward pull of the rope can force the jaws apart. The grip is released

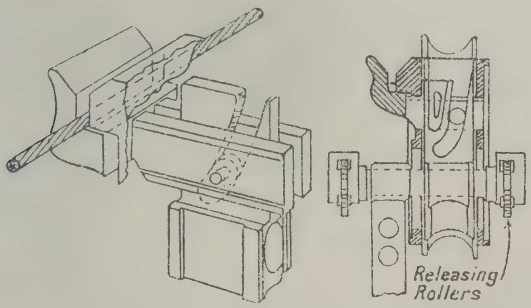

FIG. 27.

in the stations in the same manner as the type shown in fig. 26. In practice this form of grip has been found extremely simple and efficient.

In the matter of taking curves automatically in both directions, the advantage lies with the lever type of grip. In cost the latter generally has a great advantage. A ropeway, with lever grips, carrying two-ton loads on an incline of 86 per cent., is being used for carrying timber in South-West Africa.

*Costs.**

The following tables of prime and working costs for ropeways represent the standard amounts for plants possessing no peculiar complications.

* The figures given are those current some time prior to the war.

Prime Cost of Plant with Structures in Steel

Capacity in Tons per Hour.	Length of Line in Miles.			
	½	1	2	5
	£	£	£	£
5	1,900	2,000	3,300	6,900
10	2,100	2,300	3,650	7,400
20	2,350	2,600	3,900	8,000
40	2,500	2,870	5,000	10,500
60	2,850	3,200	5,700	11,900
80	3,100	3,500	6,300	13,100

The above prices are reckoned on the basis of employing spiral construction ropes up to 20 tons capacity and locked coil ropes for 40 to 80 tons capacity, and represent the total cost of the plant erected. For lengths above 5 miles a proportional cost may be taken.

Working Costs per Day.

Length in Miles.	Capacity per Day in Tons.					
	50	100	200	400	800	1,000
	s. d.	s. d.	s. d.	s. d.	s. d.	s. d.
½	17 6	21 0	25 0	32 0	42 4	48 0
1	19 5	24 0	28 10	37 7	52 0	58 5
2	26 6	31 6	36 4	49 7	68 10	76 10
5	45 7	51 0	61 0	83 3	126 0	156 10

The above costs are inclusive of depreciation, but exclusive of the cost of driving, this being so different in each case, depending on difference of height between stations, etc., that it is impossible to standardise, and it must therefore be reckoned as an extra to the above for each separate plant.

Fixed Clip Single Rope System.

This type of ropeway is only applicable for light capacities, and is used largely on plantations and for the transport of valuable ores, where comparatively small quantities are handled.

The carrier head, fig. 28, is permanently attached to the rope by means of a spring steel strap, and is designed in such a way that it can pass freely over trestle sheaves, under depression wheels and round the terminals, without being detached from the rope. As both rope and carriers are in constant motion, loading has to be done by hand, or by means of a travelling hopper, which is usually hung from overhead rails at the terminal. The terminals are extremely simple and

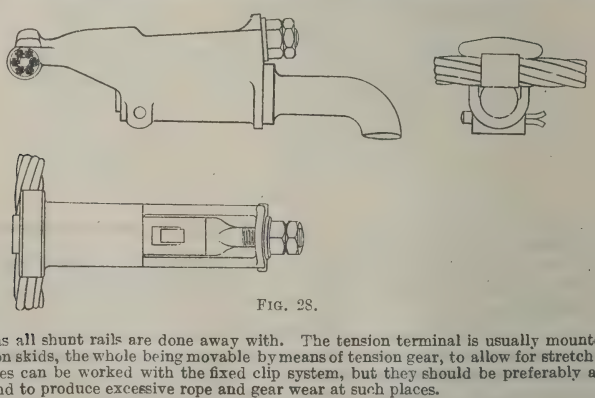

Fig. 28.

compact, as all shunt rails are done away with. The tension terminal is usually mounted on a trolley or on skids, the whole being movable by means of tension gear, to allow for stretch of rope, etc. Angles can be worked with the fixed clip system, but they should be preferably avoided, as they tend to produce excessive rope and gear wear at such places.

This type of line is run at a slow speed, namely, about 200 ft. per minute, and the only

advantages it can claim are its simplicity, adaptability to steep grades, and its low prime cost when light capacities and moderate lengths have to be dealt with.

Jig-Back or To-and-Fro.

This type of ropeway is useful for short distances, and is operated with a pair of carriers that travel in reverse directions and are loaded or brought to rest alternatively at the opposite stations, but which do not pass round the terminals: it is, therefore, intermittent in its action, and the direction of travel is reversed after each journey. Where loads are to be carried which are heavy individually in relation to the capacity, and where the distance is short, the 'To-and-Fro System' is particularly applicable. A high carrier and rope velocity may be adopted during the run, especially where a clear span occurs between terminals, and where there are no intermediate trestles. These installations may be on the 'Monocable' or 'Bi-cable' principle, and in either case the moving rope is clamped to the carriers, and is not usually disconnected from them at the terminals.

It should be mentioned that, up to the present, the 'To-and-Fro' ropeway is the only system that is used for regular passenger traffic, as the carriers lend themselves to the adoption of a safety grip used in conjunction with an auxiliary standing rope, but with such appliances these installations are very costly and present mechanical difficulties on lines of any length.

The following table, giving a rough idea of the capabilities of the various systems mentioned, shows the maximum lengths, capacities, and loads carried on various lines at present working or in course of construction:—

System.	Present Maximum Lengths.	Present Maximum Hourly Capacity.	Present Maximum Individual Load.
	Yards.	Tons.	Tons.
Monocable .	80,196	200	$1\frac{1}{2}$
Bi-cable .	38,800	250	2
Fixed Clip .	2,330	8	4 cwts.
To-and-Fro .	1,850	Passengers' weight unknown.	17 tons.

CONVEYORS.

(Contributed by Professor John Goodman, M.Inst.C.E.)

Belt Conveyors.

The horse-power required to drive belt conveyors varies so much with the design and spacing of the idlers, and the local conditions, that no accurate rules applicable to all cases can be given.

The following formula may be found useful for the average case:—

W = total weight of material delivered per minute; W_1 = total weight of belt; S = speed of belt in feet per minute; H.P. = horse-power: W_2 = maximum weight of material on belt at any one time; H = total height to which material is elevated by conveyor.

$$\text{H.P.} = \frac{(0{\cdot}15\ W_1 + 0{\cdot}07\ W_2)\ S + H\ W}{33000}.$$

An allowance of from 4 per cent. to 6 per cent. should be made for each tripper, and all other unusual elements taken into consideration. (*E. J. Haddick.*)

A belt 30 ins. wide, made up of eight plies of cotton duck faced and fitted with rubber, is known to have elevated 2,000,000 tons of coal at a South African Colony, while working at a speed of 460 ft. per min. The best performance was 3,000 tons in ten hours; no guide rollers were used.

The life of a 48-in. belt should be not less than 1,000,000 tons of coal carried. The ultimate tensile strength of a 6-ply belt, 24 ins. wide, will be about 25 tons; such a belt would work well on a conveyor when stressed to 2 tons by the tension load and drive. A rubber and fabric belt 30 ins. wide by 2,000 ft. in length, working on a conveyor nearly 1,000 ft. long, at a speed of 350 ft. per min., and loading coal at the rate of 200 tons per hour, will stand a drive of 60 h.p. when using tandem pulleys, without unduly stressing the belt. A belt 60 ins. wide, capable of carrying 3,000 tons of iron ore per hour, is quite a practical proposition.

The quality of rubber used on the working face of a belt should be capable of stretching three times its length, 3 to 5 ins., before breaking, and the belt will give the best results if in a flexible condition with the rubber rendered not too hard by over-vulcanisation. The adhesion

of the rubber face to the canvas should require a force of not less than 20 lbs. applied for one minute to separate 1 sq. in. The 'frictioning' between the layers of canvas should require a force of not less than 16 lbs. for the same purpose. The best speed for belt conveyors is from 300 ft. per min. for smaller sizes, up to 500 ft. for the larger. The speed should not be less than 300 ft., because the trajectory of the load, after leaving the belt at lesser speeds, falls too rapidly towards the vertical to ensure the whole of the stream being discharged clear of the head pulley. On the other hand, with speeds exceeding 500 ft. per min., it is difficult to deliver the load to the belt without serious abrasion.

The angle of an inclined belt should flatten gradually into the horizontal from 5 to 15 ft. (according to width) before reaching the feed from the hopper.

All inclined conveyors should be driven through worm-gearing to overcome any tendency of the belt to run back when stopped in an overloaded condition.

(*H. J. Smith*, '*The Mechanical Loading of Ships*,' *The Inst. Mech. Eng.*, *No.* 1, 1921.)

Notes on Belt Conveyors.

For conveying materials continuously over long distances in a horizontal or inclined direction band conveyors are usually employed.

Single conveyors are made up to 48 ins. in width and over 1,000 ft. in length. They can be employed for handling almost any class of material excepting those which are hot or sticky.

Solid woven cotton belts are lowest in first cost, but they are not suitable for continuous or heavy duties, because sharp substances soon cut the fabric, and, moreover, they are not waterproof and are very sensitive to climatic changes, which cause them to stretch and contract abnormally.

Belts treated with bituminous solutions are partially waterproof and resist wear much better but have the disadvantage of becoming hard, and, moreover, they will not accommodate themselves to the troughing idlers.

Balata belts, when manufactured with the true vegetable gum, are satisfactory for work in the open, as they resist damp better than any other type. The best quality belts are durable, and easily conform to the troughing idlers.

Vulcanised rubber belts of best quality, although high in first cost, are the best and ultimately the cheapest for conveying hard, heavy, or sharp materials. The cotton duck, which forms the basis, provides great tensile strength, whilst the rubber cover is the best-known material for resisting wear and abrasion. The cover on the carrying side should be at least $\frac{1}{16}$ in. thick.

Steel belts of Swedish manufacture can be obtained from 8 ins. to 16 ins. wide, and from 0·03 in. to 0·04 in. thickness. They are satisfactory for carrying wood blocks or briquettes, but are not recommended for coal, ores, or grain.

Woven wire belts of various types are used for special purposes, as for colliery picking belts, where it is desired to extract dust during conveyance.

The following table, taken from the *Engineering Magazine*, March 1909, shows the comparative values of different belts and materials to resist abrasion. Sample strips were submitted to equal sand-blast, and the volume of material worn away was measured.

Rubber belt	1·0	Woven cotton belt (high grade)	6·5
Rolled steel bar	1·5	Stitched duck (,, ,,)	8·0
Cast iron	3·5	Woven cotton belt (low grade)	9·0 to 15·0
Balata belt	5·0		

The life which may be expected from a best quality rubber belt when handling coal is given by the following expression:

$$N = 3W_b^2L$$

where,
N = the number of tons which a rubber belt may be expected to convey before it is worn out.
L = length of conveyor centres in feet.
W_b = width of belt in inches.

When estimating the life of belts made of other materials, the result obtained by the above expression must be divided by the corresponding figure in the table.

Belt Joints.—For short conveyors, endless belts may be used, but owing to difficulty of fixing they are not recommended for long conveyors. The best fastener for heavy duty is made of thin steel plates in the form of a hinge, with pins of hard copper, and used in combination with leather safes for the ends of the belt. The fasteners are secured by copper rivets.

For short and medium conveyors a satisfactory joint can be made with '**Alligator**' fasteners.

Intermediate Idlers usually consist of C.I. pulleys, 5 ins. or 6 ins. diameter, mounted on hollow shafts fixed in C.I. brackets and provided with grease lubricators.

Table I. gives the thickness of belt and pitch of idlers recommended.

TABLE I.

Width of Band.	Effective Cross-section of Material carried in Sq. Ft.		Largest Pieces Belt will carry.	Ply.	Pitch of Idlers.	
Inches.	Flat.	Troughed.	Inches.		Ft. Ins.	Ft. Ins.
12	0·04	0·09	$2\frac{1}{2}$ cubes	3 to 4	5 6 to	6 0
16	0·07	0·15	$3\frac{1}{2}$,,	4 ,, 5	5 0 ,,	6 0
18	0·09	0·19	4 ,,	4 ,, 5	4 6 ,,	5 6
20	0·12	0·22	5 ,,	4 ,, 6	4 6 ,,	5 6
24	0·16	0·34	$6\frac{3}{4}$,,	5 ,, 7	4 6 ,,	5 6
30	0·27	0·55	10 ,,	6 ,, 8	4 0 ,,	5 0

Terminal drums should have a crowned face 3 ins. wider than the belt, and the diameter should be not less than 5 times the number of plies in the belt.

The driven terminal should be mounted on a carriage controlled by weights to automatically take up any belt stretch.

The usual speeds of conveyors when handling coal, ore, broken stone, etc., are from 250 to 350 ft. per minute.

Belts are usually carried on troughing idlers for the above-mentioned materials.

Speed for handling grain, 400 ft. to 600 ft. per minute. Grain containing chaff should run at the lower speed.

Grain bands usually run on flat idlers.

The capacity in cubic feet per minute may be taken from Table I. by multiplying the effective cross-section of material carried by the speed of the belt in feet per minute.

The pitch of the idlers for the return belt should be from 9 ft. to 12 ft., according to the weight of the belt.

The power required depends on workmanship, diameter of idlers, and other factors.

If fully loaded and the conditions are good, the following expression gives the horse-power required for band conveyors:

$$\text{H.P.} = \frac{(0{\cdot}15\text{B} + 0{\cdot}07\text{M})\text{S} + \text{HW}}{33{,}000};$$

where,

B = weight of belt in pounds; M = weight of material on belt at any time in pounds; S = speed in feet per minute; H = height elevated in feet; W = weight of material delivered per minute in pounds.

DRAG BAR OR SCRAPER CONVEYORS.

These take the form of a wide chain travelling in a fixed trough, the material being dragged along by the chain bars. Considerable horse-power is required to drive this type, on account of the

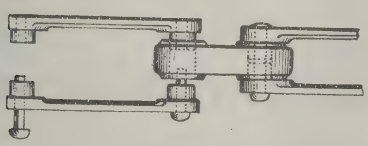

FIG. 29.

friction of the material and chain in the trough. Even with this fault the type is largely used where simplicity and few working parts are of premier importance. Examples are the 'Blackett' Conveyor, used at the coal face in collieries. The 'Bennis' Conveyor, much used in boiler stoking plants, and the 'Jenkins' 'DB' Patent Conveyor, which is principally used in gasworks for conveying hot or cold coke. It is also used for handling ashes, gravel, etc.

The conditions met with in handling coke are probably more severe than with any other material. First, because the coke reaches the trough at a temperature up to 1,700° F.;

and, secondly, the coke is of a hard cutting nature, and contains a quantity of fine particles which work into the joints. Lubricants cannot be used, and finally the conveyor is in use night and day all the year round. Yet these chains frequently have a life of from three to four years, and convey up to 130,000 tons of material.

The 'DB' Conveyor consists of a special double chain connected together with cross-bars integral with special links at intervals of 2 ft. 1½ ins., and in widths from 12 ins. to 36 ins. or more. The detail of the chain is shown in fig. 29, and as used with a trough for hot coke, fig. 30.

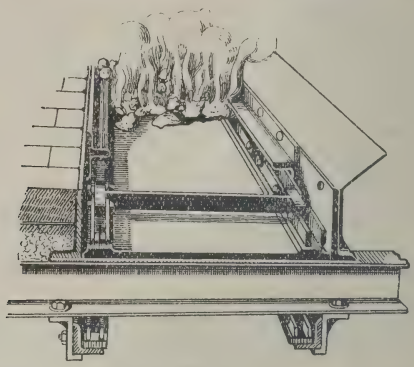

FIG. 30.

It will be noticed that special short links are used alternately with long narrow links. Only the short links bear on the trough. The usual speed of such a conveyor is from 40 to 50 ft. per minute.

A trough 2 ft. 6 ins. wide, 7 ins. deep, will convey 20 tons of coke per hour and consume about 1 h.p. per 33 ft. of horizontal length.

The conveyor will work satisfactorily on inclines up to 33°, and with special cross-bars up to 37°.

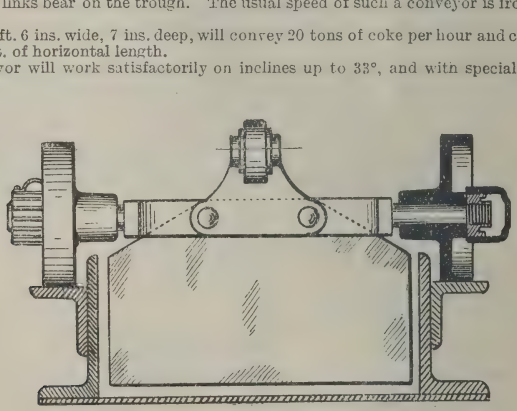

FIG. 31.

The longest single conveyor installed is 350 ft. long, on the horizontal, with the addition of 60 ft. inclined at 30°.

The power required to drive this conveyor fully loaded is 14 b.h.p.

Scraper Conveyors are mostly used for handling coal when it is desired to discharge at short intervals and when dealing with quantities of from 20 to 40 tons per hour up to a maximum length of about 200 ft. For lengths beyond this it is better to use a Pushplate Conveyor, on account of the power required to drive being so much less.

The longest 'DB' Scraper Conveyor installed is 231 ft. long, dealing with 40 tons per hour, and requires 16 h.p. when fully loaded.

Pushplate Conveyors.

These are in general use for conveying and delivering coal into storage hoppers. Conveyors of this type are superior to any other when it is desired to deliver coal at many intermediate points. For this purpose, outlets, with slide doors, are arranged in the trough where desired. Generally the chain is provided with special attachment links at intervals, which carry M.S. plates and axles fitted with C.I. rollers, and grease lubricators. The plates are kept clear of the trough so as to avoid any noise when working.

The usual speed is 100 to 120 ft. per minute, and as there is only the sliding friction between the coal and the trough the power taken is not excessive.

A typical Pushplate Conveyor is shown in section by fig. 31. For dealing with 25 tons of coal per hour the trough would be 15 ins. wide and 6 ins. deep. A single chain would be fitted with pushplates 17 ins. apart. The rollers would be grease lubricated, 6 ins. diameter and 4 ft. 3 ins. apart. A conveyor of this type, 250 ft. long, running at 120 ft. per minute, requires 5 b.h.p. to run empty, and 7 b.h.p. to run fully loaded.

Table II.—Pushplate Conveyor for Coal.

Size and Capacity in Tons per Hour.			
Width of Trough.	Pitch of Pushplates.	Depth of Trough.	Tons of Coal per Hour.
Inches.	Feet.	Inches.	
12	1·5	6	20
15	1·5	6	28
18	1·5	6	35
24	1·5	6	45

The following gives the horse-power of scraper and pushplate conveyors.

$$\text{H.P.} = \frac{KS(M + G)}{33{,}000},$$

where,
K = constant, say 0·37 for scraper and 0·13 for pushplate conveyor with rollers; S = speed in feet per minute; M = weight of material on conveyor at any one time in pounds; G = weight of moving parts of chain in pounds.

The friction of the driving gear must be added to the above.

Gravity Bucket Conveyors.

This type of conveyor is unique in the sense that one unit can transport vertically, horizontally, and at any intermediate angle, and for this reason they are much used in power-stations for elevating and storing coal in overhead bunkers.

The principle employed is a series of buckets mounted on steel spindles, which are connected to two endless chains at regular intervals, the ends of the spindles are provided with C.I. grease lubricated rollers for the purpose of travelling on horizontal rails or between inclined guides.

The buckets are suspended above their centre of gravity in such a manner that they always remain in an upright position until they are tilted by cams or levers provided for the purpose.

The corner guides for changing the direction of the chain should preferably consist of two sprocket wheels large enough in diameter to allow the buckets to swing clear of the shaft; one wheel should be keyed in place, and the other allowed to turn freely on the shaft between collars, so as to rectify any trouble that may arise should one chain stretch more than the other.

As the buckets are mounted on the chains with a space of an inch or more between, it is necessary to provide a special 'feeding device' for filling the buckets. Several types are in use, but probably the most popular is in the form of a drum having a circumference equal to at least five pitches of buckets. Outlets are arranged corresponding with the pitch, with blank plate between.

The drum is rotated by direct gear with the chain, and the material is fed through the centre. The blank plates prevent the material spilling between the buckets.

It is sometimes necessary to feed buckets at several points; in this case the filler is provided with travelling wheels to run on separate rails, and is rotated by a large sprocket wheel which engages with one of the bucket chains.

TABLE III.—SIZE AND CAPACITY OF G.B. BUCKET CONVEYORS FOR COAL.

Tons per Hour.	Pitch of Buckets.	Buckets.			Speed.
		Length.	Width.	Depth.	
	Inches.	Inches.	Inches.	Inches.	
30	21	22	16	9	45 ft. per minute
40	27	24	16	10	,, ,,
50	27	24	20	11	,, ,,
60	27	24	22	11	,, ,,
100	27	26	30	12	,, ,,

The following gives the horse-power required for gravity bucket conveyors:

$$\text{H.P.} = \frac{CH}{884} + \frac{S(W_m + W_c)}{180}$$

where,

C = capacity in tons per hour; H = height to be lifted in feet; S = speed in feet per minute; W_m = total weight of moving parts of conveyor in tons; W_c = total weight of coal in conveyor in tons.

Add for friction of gearing and motive power. (*John Goodman.*)

PNEUMATIC COAL CONVEYING PLANT.

(King's Patents.)

A system of conveying coal on the pneumatic principle, which possesses a number of advantages over the ordinary systems of coal conveying by means of bucket elevators, grabs, etc., has recently been adopted with success. In this system the coal is handled on the suction principle, a vacuum being created by means of a reciprocating vacuum pump, which produces a vacuum in the whole of the pipe line, and draws the coal from the barge or other receptacle into a 'discharger' fixed over the bunker or coal store. This discharger is arranged with a special rotary valve at the bottom which permits the coal to be discharged whilst maintaining the vacuum in the system.

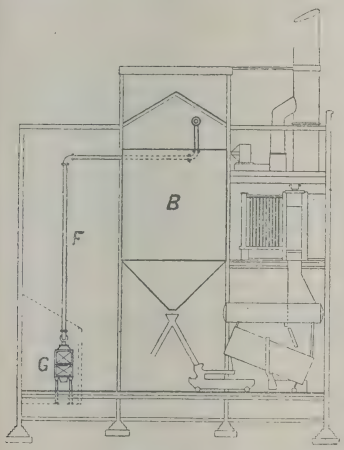

Fig. 32 shows a plant of this description which has been in operation for some time. The coal is brought alongside the power house in the barge 'A' and is elevated into an overhead bunker marked 'B.' The electrically-driven vacuum pump is marked 'C,' whilst 'D' is the 'discharger.' The first length of the coal suction pipe 'E' is flexible and fitted with a nozzle which can be moved about the barge to pick up the coal as required. The pipe between the discharger and vacuum pump marked 'F' is the vacuum pipe, and this pipe is provided with a dust collector 'G' which prevents any dust passing to the vacuum pump.

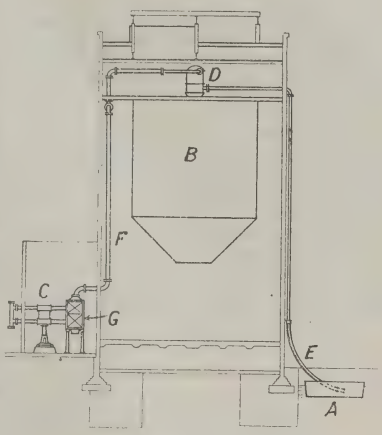
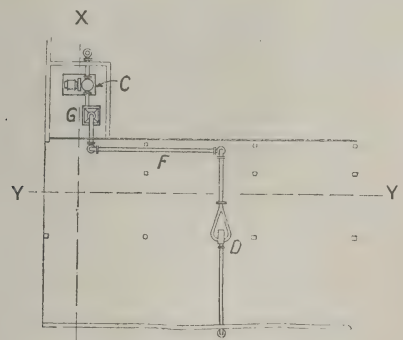
The vertical lift in the installation in question is 85 ft., whilst the vacuum required in the system from dry coal is from 6 ins. to 7 ins.



Since the apparatus as described was originally installed, an extension has been made to enable the coal to be sucked from carts on the land side of the power plant, whilst a further addition has been made for handling the ashes and flue dust.

The plant has a capacity of twenty tons per hour and the amount of power required when handling dry coal is from 30 to 35 b.h.p. It is advisable, however, to have an ample margin on the power, as more power is required when the coal is wet.



The pneumatic conveying plants are made in three capacities—namely, ten, twenty, and fifty tons per hour—and the plant is being handled by Messrs. Ashwell & Nesbit, Ltd., of London and Leicester, etc., in conjunction with Messrs. King & Co. Ltd., of Nailsworth, Glos.

Brake Linings.

FERODO APPLIED TO BRAKES.

Present-day high speeds and heavy loads require powerful and reliable brakes, these being especially necessary for modern lifting machinery. The friction coefficients of wood, leather, and metal (the materials generally used) are comparatively low, the values usually falling with heat and general working conditions; with the Ferodo lining on brakes (block, band, or disc type) the coefficient of friction increases as the temperature increases, the action is smooth

reliable and powerful, and reduces the wear and tear on the drums and gears. Ferodo fabric is readily fixed to a steel band, metal, or wood blocks. It is manufactured by *Ferodo, Ltd.*, Chapel-en-le-Frith.

For description of, and tests with, this material, see page 861.

Notes on Fabric Lining

A most important point to observe in regard to the use of fabric linings is that the blocks to be lined are first worn down so that they will make a true arc of contact, also that the fabric lining after being fitted is clear of the brake path at every point of its surface when not in action. In band-type brakes the same observations are essential, and an arrangement should be fitted whereby the top half of the band is kept well clear of the brake path by suitably arranged and powerful springs when idle.

Brake paths which are out of truth or have undue lateral play should be corrected, and the paths should be as smooth as possible. Given these conditions, experience proves that fabric linings are cheaper in the end as regards mere cost than materials which may cost little in themselves and are only costly in labour and renewal. In addition to the saving effected, there is improved efficiency, greater power, much sweeter action when engaging and disengaging, and greater durability.

In all brake paths the abutting edges should be tapered back a good 2 ins. to eliminate all possibility of any edge rising above the circumference of the path.

The manufacturers generally send out carefully printed instructions regarding fixing and applying, also as regards the correct material to use, and a little care and thought are all that are required to eliminate the possibility of failure.

SECTION XVIII

(Revised and amplified by Dempster Smith, M.Sc., M.I.Mech.E.)

PART I

BELTING—ROPE DRIVING—CLUTCHES.

BELTING.

Power Transmitted by Belting.

(*Richardson.*)

The following formula gives the power transmitted by any belt :—

$$H = \frac{(T - t)v}{33{,}000}.$$

Where

H = actual horse-power transmitted ; T = tension in lbs. on the pulling side of the belt ; t = tension in lbs. on the slack side of the belt ; v = speed of belt in feet per minute.

When a belt is doing its full work, T will be the greatest safe working tension that the belt will stand ; this is about 90 lbs. per inch of width for singles (more accurately 60 lbs. to 120 lbs., according to the thickness of the leather), and about 150 lbs. for doubles (135 lbs. for light and 160 lbs. for heavy doubles). In order that the belt shall do as much as possible, t must bear such a ratio to T that the belt just does not slip over the pulleys. In practice t varies from $\frac{1}{3}$ to $\frac{2}{3}$ of T, depending on the character of the surfaces of the belt and pulley, and on the fraction of the circumference of the pulley embraced by the belt ; $\frac{1}{2}$ of T will be a safe average value for t. Hence T − t will be on the average 45 lbs. for singles and 75 lbs. for doubles for every inch of width

Hence the following rule for finding the power that any given belt should transmit :—

Multiply the width of the belt in inches by 45 if single, by 75 if double ; multiply this again by the speed in feet per minute, and divide by 33,000 ; the quotient will be the number of actual horse-power the belt will transmit.

EXAMPLE 1.—Required the horse-power which a 5-in. single belt, running at 1,000 feet per minute, will transmit.

$$\frac{5 \times 45 \times 1{,}000}{33{,}000} = 7 \text{ horse-power (nearly).}$$

EXAMPLE 2.—What power can be transmitted by a 12-in. double, running at 1,500 feet per minute ?

$$\frac{12 \times 75 \times 1{,}500}{33{,}000} = 41 \text{ horse-power (nearly)}$$

EXAMPLE 3.—An example of the reverse kind: What width must a belt be to transmit 20 horse-power, the belt running at a speed of 2,500 feet per minute?

$$\frac{20 \times 33{,}000}{2{,}500 \times 45} = 6 \text{ ins. nearly, if single.} \qquad \frac{20 \times 33{,}000}{2{,}500 \times 75} = 3\tfrac{1}{2} \text{ ins., about, of double.}$$

The values given in the table are more accurately calculated, and hence do not exactly agree with the above examples.

The size of the pulleys or the number of square inches of contact between belt and pulleys has no effect on the power transmitted; that is to say, the same belt will have just as much grip, other things being equal, on 1-foot pulleys as on 4-foot pulleys. The fraction of the circumference of the pulley embraced by the belt, however, has an important effect on the friction between the two; that is to say, if the belt is in contact with the pulley for more than half the circumference of the latter it will get a better grip, and will therefore transmit more power than if in contact for less than half the circumference; hence the desirability, where possible, of making the pulling half of the belt the lower one, so that the slack upper side may sag down and lap further round the pulley.

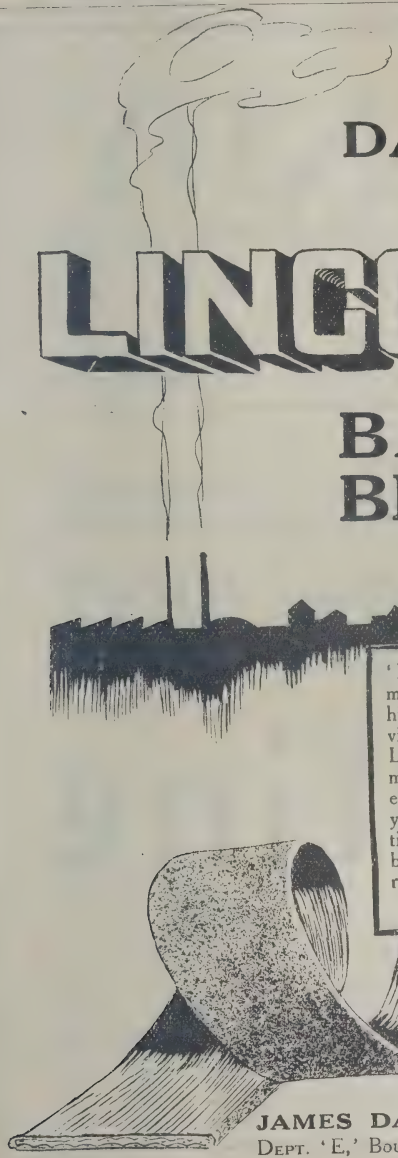
The following table gives the number of horse-power which belts of various sizes should transmit. Allowance has been made for the loss of power at high speeds, due to the centrifugal force of the belt. This loss is negligible at low speeds, but increases with the velocity, amounting to about 10 per cent. at a speed of 3,000 feet per minute, and about 30 per cent. at 5,000 feet per minute; no advantage is gained by running a belt faster than 4,000 or 5,000 feet per minute.

Under very good conditions of working, belting will transmit up to 1¼ times the amounts given in the following table without being overstrained.

TABLE SHOWING HORSE-POWER TRANSMITTED BY LEATHER BELTS UNDER AVERAGE WORKING CONDITIONS.

Speed of Belt. Ft. per Min.	Width of 'Single Thickness' Belts (ins.).									
	1	2	3	4	5	6	7	8	9	10
500	0·67	1·4	2·2	3	3·7	4·5	5·2	5·9	6·7	7·4
600	0·81	1·7	2·6	3·6	4·5	5·4	6·3	7·2	8·1	9
700	0·93	2	3	4·1	5·2	6·2	7·3	8·3	9·2	10·4
800	1·1	2·2	3·5	4·7	5·9	7·1	8·3	9·4	11·6	11·8
900	1·2	2·5	3·9	5·4	6·7	8	9·4	10·7	12	13·4
1,000	1·3	2·8	4·3	5·8	7·3	8·8	10·2	11·7	13·1	14·6
1,500	2·0	4·1	6·3	9·5	10·8	13	15	17·3	19·4	21·6
2,000	2·6	5·5	6·7	11·4	14·3	17·1	20	22·8	25·7	28·6
2,500	3·2	6·8	10·4	14·2	17·7	21·2	25	28·4	32	35·4
3,000	3·8	8	12·3	16·8	21	25	29·5	33·5	38	42
3,500	4·3	9·2	14	19·2	24	29	34	38·5	43	48
4,000	4·8	10·4	16	21·8	27·2	32·5	38	43·5	49	54·2
4,500	5·4	11·4	17·5	24	30	36	42	48	54	60
5,000	6·0	12·5	19·3	26·5	33	40	46	53	60	66

Light 'double thickness' belts will transmit 30 per cent. more power than that given in the above table.



For ordinary 'double thickness' belts the values given in the table may be increased 50 per cent., whilst for extra heavy 'double thickness' belts the values given in the table may be increased 70 per cent.

For intermediate speeds, and widths of belt, the h.p. transmitted is proportional to the speed or width of belt.

DAWSON'S

LINCONA

BALATA BELTING

'LINCONA' Balata Belting is manufactured throughout from highest grade materials and provides at a **cost less** than that of Leather Belting a power transmitter of great strength and unique efficiency. A trial will convince you that 'Lincona' can save many times its cost in a very short time by the reliability of the service rendered and freedom from expensive Belt stoppages.

Note.—This table may be thoroughly relied upon for all ordinary conditions of working. The results of tests made by Chas. Hopkinson, M.Inst.C.E., M.Inst.M.E., B.Sc., show that the 'Camel' Brand belt working under favourable conditions will safely transmit double the horse-power given in the above table.

Turner Brothers' Hair Beltings.

'Tower' Hair Belting (*Turner Brothers Asbestos Co. Ltd., Rochdale*) is a standard quality made from the finest yarns; 'Gripwell' Hair Belting is a cheaper, but reliable grade. 'Perfex' Hair Belting is a type with a hardened cotton edge, and has been specially designed for driving cotton-spinning machinery, such as mule down drives, top straps, and ring spinning frames, or heavy forkwork generally.

Cross Section of Belts.

The following table shows what area of cross section of leather belt is needed to give various horse-powers, with various arcs of contact on cast-iron pulleys, at a belt speed of 3,000 feet per minute, the fastenings being single leather lacings. From it, having decided on the thickness, the width may be determined, or *vice versa*, by simple division:

Arc Contact.	Horse-powers.									
	5	10	15	20	25	30	35	40	45	50
Deg.	Sq. in.	Sq. in.	Sq. in.	Sq. in.	Sq. in.	Sq. in.	Sq. in.	Sq. in.	Sq. in.	Sq. in.
30	0·90	1·79	2·68	3·58	4·48	5·37	6·27	7·16	8·06	8·95

Belt Tension.

To find out whether the force carried by a belt is more than should be properly put upon it, or upon its fastening, we must know how much the arc of contact is, and what the tension on both the tight and the slack folds. The greatest tension upon it is that in the tight fold or side; and this is equal to that on the slack side plus the pull which the belt gives to the pulley or which the pulley gives to it. The greater the arc of contact, the greater the ratio between the tight and the slack side, and the less the tension will be upon the belt and its fastening to transmit a given power at a steady speed. Thus, if we have a pull of 10,000 lbs. necessary to carry a certain horse-power, when the arc of contact of the belt on the pulley is 90°, that means that the ratio between the tension on the tight side and that on the slack side is 1·874; in other words, for every pound upon the slack side there will be 1·874 lbs. on the tight side; and if the difference between the tensions on the slack and the tight sides be 1,000 lbs., it will be necessary to have 1,000 ÷ 0·874 = 1,144 lbs. tension on the slack fold, and 2,144 on the tight one. (These figures apply to leather belts in good condition upon cast-iron pulleys, also in good condition.) The following table shows the ratio between the tension and transmitted pull for various arcs of contact from 30° to 300°:—

TABLE OF GREATEST TENSION ON BELTS.

Degrees of Arc . .	30	45	60	75	90	105	120	135
Ratio between tension and transmitted pull .	5·29	3·71	2·92	2·45	2·14	1·93	1·77	1·64
Degrees of Arc . .	**150**	**165**	**180**	**195**	**210**	**240**	**270**	**300**
Ratio between tension and transmitted pull .	1·54	1·47	1·40	1·35	1·30	1·23	1·18	1·14

EXAMPLE.—If it takes a pull of 300 lbs. to carry a given horse-power when the arc of contact is 195°, then the tension upon the tight side will be 1·35 × 300 lbs., or 405 lbs. Expressing results in horse-power instead of pounds pull, suppose that it is necessary to carry 175 horse-power with a belt running 2,000 feet per minute, and having 210° arc of contact; then the pull on the pulley will be 33,000 × 175 ÷ 2,000 = 2,887 lbs.; and the greatest tension upon the belt will be 2,887 × 1·3 = 3,753 lbs.

For double leather main belts, H.P. = $\frac{80 \text{ W V}}{33{,}000}$ where W = breadth in inches, V = velocity in feet per minute.

General Rules for Belts.

(1.)

A good all-round rule, and one easily remembered for belt calculations, is that 1 ft. per minute of belt speed per inch of width of belt is safely equal to the transmission of 1 watt of electrical energy. If we therefore multiply the belt speed is feet per minute by the width in inches, the result will be the total energy in watts; and if we divide the result by 1,000, the energy is obtained in kilo-watts, which energy the band may be relied upon to transmit without any undue tension being brought upon any part of the belt or excessive friction in any part of the machinery. These data, however, only apply to single leather belting or to woven belting of a similar thickness. If a light double band be employed, then 25 per cent. more energy may be calculated upon; or for heavy double leather belting as much as 60 per cent. more may be added. The great advantage for this method of calculation is that it fixes a constant for working tensions, so that the working tension becomes directly proportional to the width in inches, this constant being 44·24 lbs. pull per inch width of belt. If we wish, therefore, to know the difference in pounds pull on the tight and on the slack side of any belt, all that is necessary is to divide the total output of the machine in watts by the velocity of the belt in feet per minute, and multiply the result by 44·24, and the product will be the extra pull in pounds on the tight over the slack side. (*R. Berry.*)

(2.)

One horse-power will be transmitted by a single thickness belt 1 inch wide running at the rate of 1,000 feet per minute.

A belt $\frac{1}{10}$ths of a square inch section will transmit 1 horse-power at the foregoing rate.

Tension on belt by either of these rules will be 33 lbs. per inch of width and 165 lbs. per square inch of section.

With belts in good working order the frictional hold on the pulleys is about 58 per cent. of the pressure of the belt on the surface of the pulley as a maximum, and about 42 per cent. under ordinary atmospheric conditions.

It is safe to reckon that a double belt will do half as much work again as a single one.

Belting made of Helvetia leather is much stronger and will bear a heavier load than that made from ordinary tanned leather.

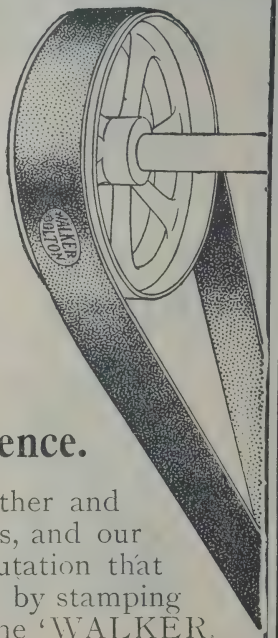
COLE'S BALATA BELTING

FOR ALL CLASSES OF

DRIVING & CONVEYORS.

BALATA & TEXTILE

Belting Manufacturers,



HENRY A. COLE & Co. Ltd.

"A" DEPT.,

CORONET WORKS,

LIVERPOOL, ENGLAND.

A Century's Experience.

We have been tanning leather and making Belting for 100 years, and our products have gained a reputation that we value. We safeguard it by stamping all our Belting with the name 'WALKER. BOLTON.'

Let this name be your guarantee also, and you will be assured of a Belt that will transmit maximum power with long life and freedom from breakdowns.

Write for copy of 'The Belting Book,' which gives full particulars of our various brands of Belting; sent post free on request.

WM. WALKER & SONS LTD.

BOLTON. ENGLAND.

℗ H.16

A double belt is more serviceable upon pulleys of large than upon those of small diameter, and should not be used upon pulleys whose diameters are less than about 3 times the width of the belt, unless the belt width exceeds about 4 ins.

Rubber belts will transmit from 25 to 40 per cent. more power per given arc of contact than leather belts. They should not be used in situations where they will be subject to a temperature of over about 90° F.

The average weight of a good four-ply rubber belt 7 ins. wide is 16 ozs. per linear foot. The best rubber belting is made with 32 ozs. duck, and then weighs 20 ozs. per linear foot.

It is a common error among mechanics and owners of factories to make the face of their pulleys narrow, in order to economise on the first cost of belting; but this false economy seldom decreases the cost of the machinery, and only saves a trifle in the first cost of belting. The small amount saved is soon lost by the stopping of machinery caused by the slipping of belts, strain on the shafting, increased friction (requiring additional driving power), and rapid destruction of the belts themselves. Were pulleys made of a proper size and width and face, and belts of proper width run with the *grain* side of leather to the pulley, a considerable saving of coal might be effected annually, and an immense amount of trouble avoided.

Leather belts with grain side to pulley can drive 34 per cent. more than flesh side.

(3.)

To find the diameter of driving pulley.—Multiply the diameter of the driven by the number of revolutions it should make, and divide the product by the number of revolutions of the driver.

To find the diameter of driven.—Multiply the diameter of the driver by its number of revolutions, and divide the product by the number of revolutions of the driven.

To find the number of revolutions of the driven.—Multiply the diameter of the driver by its number of revolutions, and divide by the diameter of the driven.

To find the horse-power of a pulley.—Multiply the circumference of the pulley (feet) by the revolutions per minute, and the product thus obtained by the width of the belt, and divide the result by 600. The quotient will be the horse-power.

Length of Belts.

(1.)

(Not crossed.)

RULE.—Add the diameter of the two pulleys together, divide the result by 2, and multiply the quotient by $3\frac{1}{4}$; then add this product to twice the distance between the centres of the shafts; the result is approximately the length required.

(Crossed.)

RULE.—Mark off by lines the pulleys, set at their proper distance apart (either full size or to scale), and measure the length of the side of the belt, supposing the belt to envelop one-half the circumference only of each pulley, and add to this one-half the circumference of each pulley. If there is a great difference between the relative diameters of the pulleys, and the distance apart of the shafts is unusually small, the length of the straight sides of the belt should be measured, and the arcs of contact around the pulleys stepped around by compasses, the set of the latter being not more than about one-tenth the circumference of the pulley.

In the case of both running horizontally, the upper half of the belt should be the driving side.

(2.)

(Auguste Esnouf, A.C.G.I.)

Let X = distance between centres of pulleys; D and d = respective diameters * of pulleys; C and c = respective circumferences; P = a parameter equal to D − d for open, and to D + d for crossed belts, exclusive of lap for jointing; L = length of belt. Then

$$L = \tfrac{1}{2}(C + c) + 4X - \sqrt{4X^2 - P^2},$$

with an approximation such that the relative error is less than 1 in 1,000 for values of the ratio $\frac{X}{P}$ greater than or equal to 1·5; the relative error is about $\frac{1}{2}$ per cent. when $\frac{X}{P} = 1$.

For exact results, $L = \frac{1}{2}(C + c) + KX$, for both open and crossed belts; and $L = mX$ for crossed belts, where K and m are coefficients, tabulated herewith for the various values of the ratio $\frac{X}{P}$.

* Strictly speaking, D and d should be the theoretical diameters—that is to say, actual diameters plus thickness of belt.

$\frac{X}{P}$	K.	m.	$\frac{X}{P}$	K.	m.	$\frac{X}{P}$	K.	m.	$\frac{X}{P}$	K.	m.

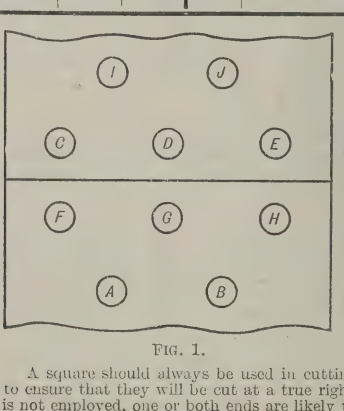

FIG. 1.

Jointing Belts.

LACED BUTT JOINT.

For belts about 3 ins. wide and over, the holes C, D, E, and F, G, H, should be about 1 in. apart and $\frac{3}{8}$ in. from the line of joint; A, B, and I, J should be about $\frac{1}{2}$ in. behind C, D, E, and F, G, H, respectively.

The sizes of the holes should be as follows:

Width of belt up to 4 ins. Size of punched hole, $\frac{1}{4}$ in.
" " from 4 to 8 ins. " " $\frac{5}{16}$ in.
" " " 8 ins. upwards " " $\frac{3}{8}$ in.

WIDTH OF LACES.

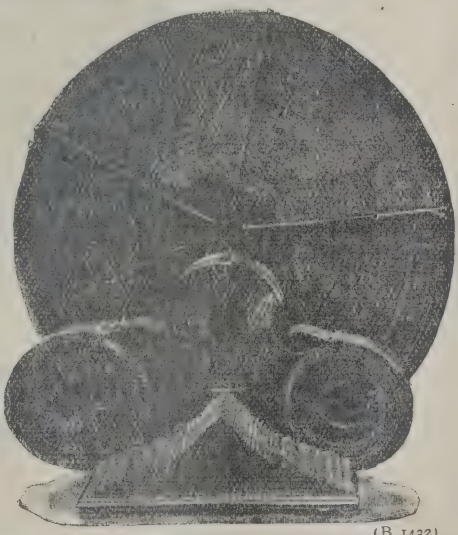
Width of belt 24 ins. and over. Width of lace, $\frac{1}{2}$ in.
" " 6 to 24 ins. " " $\frac{3}{8}$ in.
" " 2 to 4 ins. " " $\frac{5}{16}$ in.
" " 2 ins. and less " " $\frac{1}{4}$ in.

A square should always be used in cutting the ends of a belt preparatory to joining them, to ensure that they will be cut at a true right angle to the centre line of the belt. If a square is not employed, one or both ends are likely to be cut uneven or irregular, and these conditions cause the belt to slip from side to side of the pulley and impose irregular strains on the belt fibres, which no belt can endure indefinitely. Belts of widths up to about 18 ins. can be cut sufficiently true by holding one leg of the square against one side of the belt, having the other leg project across the belt, and then cutting along the edge of the latter with a sharp knife held perpendicular to the belt. The knife blade should be made wet occasionally to make it cut easily.

The ends of wide belts are difficult to cut square on account of slight variations in their widths and because the sides may not be exactly parallel; satisfactory results may be assured by the following method: At any point on the belt near where it is to be cut, measure across and find the centre, then at a point 2 or 3 ft. back from these dimensions, locate the centre again, and between these two points draw a clean sharp line. Next, by holding one leg of a square against the centre line just made, trim off one-half of the end of the belt by cutting along the other leg. By laying the square on the other side of the centre line, the other half of the belt can be cut. The square should be held firmly in position while cutting the belt, and if two small nails are driven in the belt on the centre line, they will help to keep the square from slipping.

JOINING THIN BELTS.

Place two ends of belt together, with edges fair one with the other, and make with an awl a row of holes, at *a*, through both ends. Then take about half a yard of strong twine, and



NORTH BRITISH
RUBBER BELTING

is used in all parts of the world both for driving and conveyor purposes.

It was first introduced sixty years ago and has a world-wide reputation for high quality and long wearing properties.

Rubber Belts are superior to leather and resist damp and warm atmospheres better than any other kind.

'NORTH BRITISH' Rubber Belting means stronger running, increased power and less wear and tear on the machinery, and longer life.

Write for Lists and interesting Booklet giving much valuable information to Belt users.

North British Rubber Co. Ltd.
Castle Mills,
EDINBURGH.

(B 1432)

NORTH BRITISH

Rubber Goods

of every description for mechanical engineering, scientific and other purposes, are pre-eminent in the opinion of discriminating users in all parts of the world and are made in the largest rubber factory in the British Empire. The wide range of rubber and vulcanite articles include :

Rubber Hose

Delivery, Air, Drill, Suction, Gas, Steam, etc.

Valves

Gaskets, Washers, Gauge Glass Rings, etc.

Vulcanite

Rod and Sheet, High Resistance Vulcanite for Wireless, Telephone Fittings, etc.

Rubber Belting

Transmission and Conveyor.

Rubber Boots and Shoes

North British 'Clincher' Tyres

Pneumatic and Band Tyres for Cycles, Cars, and Heavy Motor Vehicles.

'Paraflor' Rubber Carpeting.

CASTLE MILLS EDINBURGH

London Warehouse and Export Depot :
204 Tottenham Court Road, London, W. 1.

Warehouses in all large Cities at Home and Abroad.

draw half the length through the first hole; then pass each end of the twine through the second hole, one to the right and the other to the left, and draw both tight at the same time,

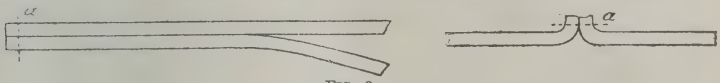

FIG. 2.

and so on until the last hole is reached, when one end only of the twine is passed through. The two ends of the twine are then knotted together, and the excess cut off.

LAP JOINTS.

FIG. 3.

Cut down overlap to a plain bevel, cement surfaces together, and insert small taper wooden pegs, such as are used for boot and shoe manufacture. This is the strongest form of joint that can be made.

LENGTH OF LAP.

Width of single belt, in inches .	1 to 4½	5	6 to 8	9	10 to 14	15 to 24
Length of lap, in inches . . .	4½	5	6	6½	7	8

All double belts should have a 6-inch lap at least.

CEMENT FOR BELT JOINTS.

Equal parts of good glue and American isinglass; place the material in a glue pot and add sufficient water to cover the whole. Let the mixture soak ten hours, then bring the whole to a boiling heat, and add pure tannin until the whole appears like the white of an egg. Apply warm. Buff the grain of the leather where it is to be cemented, keep the joint surfaces pressed firmly together, let the joint dry for a few hours, and the belt will be ready for use.

(*Railway and Locomotive Engineer.*)

Belt Dressings.

A preparation (*Sterns, Ltd.*) made in brick form is sold under the name of 'Balagrip' for Balata belts, and 'Sternol' bricks for leather belts. It prevents slipping, and enables belts to be run slack, thus increasing their driving power and lengthening their life. It is packed in cases containing ten bricks of 2 lbs. each; sample orders for a single case on approval are supplied.

'Gripwell' Belting Syrup (*Turner Brothers Asbestos Co. Ltd., Rochdale*) is particularly suited for fast and loose drives or shock drives, to prevent slip; the dressing is applied hot, so as to penetrate the belt freely.

Oiling and Greasing Leather Belts.

When the belt is pliable, and only dry and husky, apply blood-warm tallow, and dry in by heat of fire or sun. The addition of resin to the tallow for belts used in wet places is advantageous. Belts which have become hard and dry should have an application of neatsfoot or cod-liver oil mixed with a *small* quantity of resin.

Suggestions to Belt Users.

In order to obtain a given amount of power, it is better to use a narrow belt running at a high speed than a wide belt running at a low speed.

If possible, use a belt speed of about 3,000 feet per minute for smaller powers, and about 4,000 feet per minute for high powers. Thrashing machine belts run at about 2,200 feet per minute, and this is the usual speed for agricultural machines.

Use a pulley that is wide enough so that a small amount of irregularity in the belt does not make it run off. Allow at least ½ in. on machine pulleys and 1 in. or more on countershaft and lineshaft pulleys. Use crowned pulleys wherever possible.

If possible, use a horizontal belt with large centre distances and with the pulling side at the bottom. In a horizontal drive, the slack side of the belt at the top of the drive increases the belt contact.

When using a vertical belt, do not have more centre distance than is absolutely necessary, because the weight of the belt reduces the efficiency of the drive.

Avoid crossed belts on short centre distances. Avoid the crossing of wide belts. If it is necessary to cross belts, see to it that the rubbing of the belt surfaces does not have a tendency to open up the laps.

Keep belts flexible and as clean as possible. Do not use belt dressing containing mineral oils or resins.

Hints on Belt Driving.*

(John Tullis & Son, Ltd., St. Ann' Works, Glasgow.)

Pulleys having a high convexity prevent the belt from grasping its work. One-sixteenth of an inch is sufficient convexity for pulleys 6 ins. wide and under ; $\frac{3}{32}$ of an inch is enough for pulleys over 12 ins. wide.

By compounding two single or double belts the gain in horse-power is close on 100 per cent.

By compounding three single or double belts the gain in horse-power will be close on 200 per. cent.

Double belts should never be run on pulleys of small diameter. Compound single belts give much better results as regards power, longer life, and less cost.

Compound belts save the cost of wide pulleys as well as the room of wide pulley space.

Every inch in width of good double leather belting, travelling at 500 ft. per minute, while working on pulleys 24 ins. diameter, will transmit one horse-power, provided the arc of contact is 180 degrees.

Every inch in width of good single leather belting, travelling at 800 ft. per minute, while working on pulleys 24 ins. diameter, will transmit one horse-power, provided the arc of contact is 180 degrees.

A comfortable working strain for a single belt is about 50 lbs. for every inch of breadth, and for a double belt 80 lbs.

A belt running with the soft flesh side next the pulley will wear longest, because it is working according to the natural growth of the hide.

When driving on pulleys of 4 ins. diameter and under, the belt ought to be barely $\frac{1}{4}$ in. thick. On pulleys 4$\frac{1}{2}$ ins. to 8 ins. diameter the belt should be about $\frac{5}{16}$ in. thick. On pulleys 8$\frac{1}{2}$ ins. to 12 ins. diameter the belt should be about $\frac{3}{8}$ in. thick. On pulleys 12$\frac{1}{2}$ ins. to 18 ins. diameter the belt ought to be barely $\frac{1}{2}$ in. thick. On any diameter above 18 ins. heavy leather can be used with profit.

If the slack side of a main driving belt runs in wave form it is certain that the engine is getting more steam on one side of the piston than on the other. This unsteadiness is transmitted to all the working belts in the factory.

A badly balanced pulley, running at a high speed, will impart an unsteady motion to the belt running on it. The machine so driven makes bad work.

When a belt gets saturated with waste oil, an application of ground chalk will soon absorb the oil and make the belt workable.

Where possible, all belts should be run with the driving or tight side under the pulleys. The sag of the upper or slack side helps the belt to hug the pulley to the extent of 20 per cent. gain in driving power, as compared with a belt running with the tight side uppermost.

Belts running over pulleys of small diameter at high speeds ought to be as thin and as wide as possible. Orange-tan leather of uniform thickness answers remarkably well.

HIGH-SPEED BELTS.—A belt made from selected orange-tan leather, not too thick, softened, and made flexible, is the toughest and best leather belt for this class of drive. This belt will transmit great power when running at a belt speed of six to nine thousand feet per minute. The pulleys used for such drives must be strong and equally balanced, carefully turned to template, having a convexity no higher than one-sixteenth of an inch. Such pulleys must be hung perfectly true to each other upon the driving and driven shafts.

Thin belts, as wide as possible, give by far the best results working vertically. A thick vertical belt will not hug the pulleys.

In the use of vertical pulleys and guide pulleys, these pulleys ought to be twice the width of the belt, having no flange.

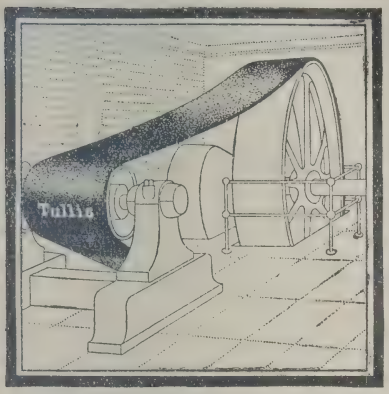
For machinery requiring the continuous shifting of the belt, single orange-tan leather is too thin, but double is highly recommended.

Leather link belting cut from the butt and made concave to suit the convexity of the pulleys will transmit from 25 to 30 per cent. more power than a flat belt.

Orange-tan leather rope, 1 in. square, running at 1,000 ft. per minute, on pulleys not less than 4 ft. in diameter, will transmit 10 horse-power.

In lacing hair belts the laces should run in parallel lines, each row laced separately, and no stitches placed across between the rows.

A circular saw belt ought not to be narrower than one-fourth of the diameter of the saw. The spindle pulley should be as great in diameter as the width of the belt.



The following show tensile breaking stresses of leather belting :—

British Oak-tanned . . .	4500–5000 lbs. per sq in.
British Orange-tanned . . .	6000–6500 " "

Belt Pulleys.

These should be at least an inch wider than the belt, and the rim should be convex to keep the belt in the centre ; about $\frac{1}{16}$ in. to $\frac{3}{32}$ in. of convexity is usually allowed in pulleys up to 12 ins. wide and over. The ratio of the diameters of two pulleys which work together should not

* Abstract from 'Guide to Belt Driving.'

'Tullis' gives you service.

You can Depend on the Quality

Under the most severe conditions of service.

Our whole aim is to sell you not *more* Leather Belting but—the *right* Belting for your particular requirements.

Our reputation for Leather Belting of surpassing excellence is world-wide and unique.

To maintain that reputation unimpaired is our constant aim.

exceed 6 to 1. The distance apart should, if possible, be such that the arc of contact on the smaller pulley is not less than 165°. If the arc of contact is less the width of the belt should be increased (see page 833). The diameter of pulleys is seldom less than 50 times the thickness of the belt in the case of ordinary belts, or 30 times the thickness of link belts; that is, if any reasonable amount of power is being transmitted.

The slip in the case of a wood pulley with a single-ply oak-tanned leather belt is less than with one of cast-iron, if the belt tension is low.

Belt Driving with Quarter or Right Angle Twist.

Fig. 4 shows the arrangement of pulleys for this purpose. In this case the centre of the bottom pulley should be in a dead line with the left-hand circumference of the top pulley, and the left-hand circumference of the bottom pulley should be in a dead line with the centre of the top. This is the correct position, but in actual practice the position of both pulleys has to be sometimes slightly altered to suit the running of the belt; this is a very simple matter, as it only means moving the pulley along the shaft one way or the other until it is seen that the belt

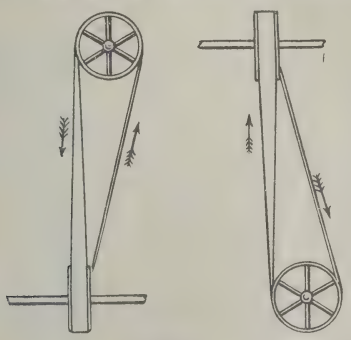

FIG. 4.

is in contact with the face of the pulley. No 'guide' pulleys are necessary. The pulleys should preferably be slightly crowned, i.e. a little larger in diameter at the middle than at the edges.

Link belts are not generally used for this kind of drive, but flat belts made with a special curve to suit the drive in question; the curve of the belt varies according to the diameter of the pulleys, one to each other, and also to the length of centres.

PUTTING ON HEAVY BELTS.

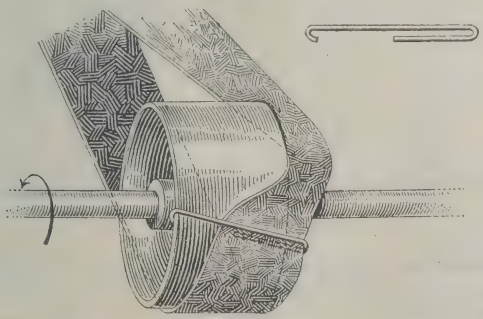

FIG. 5.

Fig. 5 shows a simple device for putting on heavy belts when it is necessary to shut down in order to do so, and where a rope is usually employed for the purpose.

Take a piece of $\frac{1}{4}$- or $\frac{5}{16}$-in. round iron and bend it, as shown in the small sketch. Hook the H H

short end over the edge of the rim of the pulley and the long end under the belt as indicated. Start the engine slowly, and when the belt is on it is not necessary to stop, because the short end of the hook will straighten out and disengage itself. It is a good plan to use a rod of as light weight as will answer the purpose, since it will straighten out and free itself with less stress on the belt; the iron hook then falls to the floor. (*Power.*)

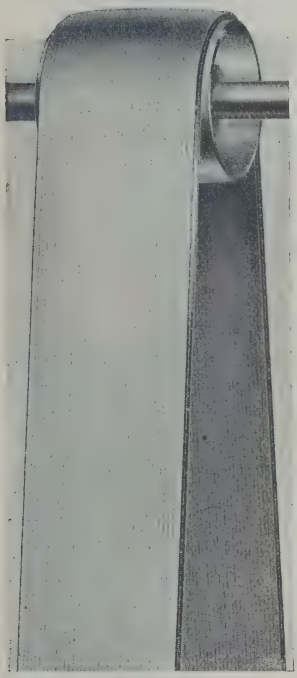
BALATA BELTING.



'Veelos' Balata Belting (*Turner Brothers Asbestos Co. Ltd., Rochdale*) is a type suitable for the heaviest driving, conveying, and elevating of all descriptions; it is unaffected by atmospheric conditions, and does not contract on the pulleys when at rest.

HENDRY

FROM A SINGLE STRAND

BELTING

PATENTED ALL OVER THE WORLD.

Efficiency in Power Transmission
a Vital Factor
in National Reconstruction.

Before the War the merits of the HENDRY BELT were recognised by foremost users at home and abroad, including the British Admiralty, War Office, India Office, Ordnance Works, Shipyards, Electric Power Plants, Mining Companies, Engineers, and scores of others. . . .

During the War the HENDRY BELT was the transmitter of power to tens of thousands of Light and Heavy Lathes and Machine Tools, Planing Machines, etc., etc. . . . . .

Millions of the Allies' steel messages of "Friendship" to the Bosche Lines owed their spinning flight to HENDRY BELTS in Shell and Gun Factory. . . Whilst our dauntless Bird-men winged their way by wondrous Engines shaped in tools of precision driven by Hendry. . . . . .

With Peace Driving Efficiency becomes a matter of urgent National moment, its Study, the patriotic and practical duty of every power user. . . A knowledge of the HENDRY BELT, its unique patented construction and remarkable efficiency is therefore an essential to the heads of all progressive plants. . . . . .

The Hendry Patent Construction,—the Secret of Hendry Efficiency

HENDRY

FROM A SINGLE STRAND

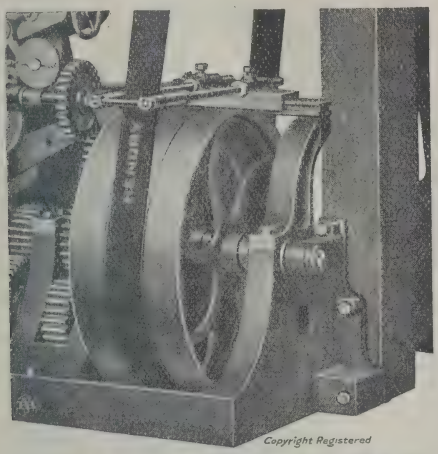
BELTING

One of the leading Electrical Engineers of the day describes the HENDRY Patent Laminated Leather BELTING as forming a true Endless Belt, which is adaptable to universal service. . . . . .

The Hendry ENDLESS SPLICE forms a joint identical in Texture, Thickness, Flexibility and Driving Grip with the belt itself. . . . A HENDRY BELT runs without jar, vibration, or slip under the heaviest load and at the highest speed. . . . . The new Patent Hendry Belt effects a marked saving in the consumption of Electrical Power per H.P. transmitted. . .

THE HENDRY SIMPLE HORSE POWER DATA

As every Drive is in a measure a law unto itself, it is difficult to furnish a detailed table of Horse Powers which is universally applicable. The following simple data will, however, enable the working out of any particular condition, and will ensure satisfactory driving with a fairly average life to the belt. . . . . The calculations are based on the transmission of 1 H.P. per lin. of width at the various speeds for each number of thickness of belt, working over pulleys 18in. diameter.



With Driving Side on BOTTOM:

HENDRY

FROM A SINGLE STRAND

BELTING

For Planing Machine, Lathe and all Heavy Machine Tool Driving the HENDRY new patent Flexible construction gives a peculiar Elasticity and Spring not found in any other Belting, which acts as a cushion against heavy and irregular stresses, and reduces stretching and wear to a minimum. . . . . The largest concerns at home and abroad have conclusively proved that HENDRY belting permits of higher speeds, heavier cuts, steadier running and an all round increase of output. . .

STANDARD SIZES OF HENDRY BELTING.

The Hendry Belt is made to meet every requirement, in Seven standard Weights from ¼in. to 1in. thick and from 1in. wide to 48in. and upwards. . . Whatever your Driving Problems, Hendrys' expert advice and assistance is freely at your service. . . Write for the Book of the Hendry Belt, post free.

F. 841

Solid Woven 'Gripoly' Belting.

The edges of this belting (fig. 6) are composed of indestructible strands, twisted and interwoven with the solid body of the belt; this prevents all fraying, so that the belt runs under the same conditions as solid leather. The 'gripping' power is very marked, and, being quite water-

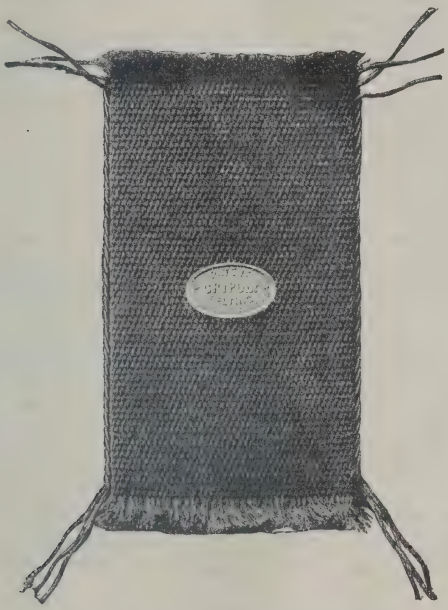

Fig. 6.

proof, the material is not in any way affected by temperature, nor by acids, steam or dust. It is claimed to be practically stretchless. The belting can be jointed like any other belt, and is quite straight running.

Steel Belting.

Steel belts have been recently introduced for the purpose of transmitting power, and are in somewhat extensive use on the Continent. These belts are from $\frac{2}{10}$ to $\frac{5}{10}$ mm. thick, and from 22 mm. to 200 mm. wide, as required. The steel for such belts is of a very high temper and is manufactured specially for this purpose. The difficulty of jointing the belt is one of the great objections. At present the joint is generally made by the makers, and is usually effected by soldering the ends to a keep plate on both sides of the band, and made doubly secure by screws. The length of the belt is obtained by stretching a special tape to a predetermined tension across the pulley, and both ends of the tape are cut at the overlap.

These steel bands run quite well on the bare pulley, but there is a tendency to polish the same and it is therefore desirable to cover the pulley with a very thin cork covering, which is glued on to canvas which in turn is cemented to the pulley. With this arrangement there appears to be little or no slip whatever. This is proved in practice by the fact that the cork covering does not wear away.

With such a belt, 32 mm. thick by 0·3 mm. thick, and cork-faced pulley, Prof. Kammerer, of the Charlottenburg University, transmitted 26·3 h.p. at a speed of 15·7 metres per second. Both pulleys were 1,250 mm. diameter, and the slip was equal to 0·91 per cent.

ROPE DRIVING.

For main driving, the ropes used are now almost exclusively made from cotton. For small drives, such as are used in cotton mules, ring frames, cream separators, etc., cotton ropes are used to the exclusion of all others.

The advantages which a cotton rope has over those of Manilla hemp are:

Greater Flexibility.—They can thus be used over smaller pulleys, or when run over large pulleys suffer less wear.

Superior Resilience.—They absorb shocks without detriment, and have thus less tendency to slip in the grooves.

Greater Driving Power for the same diameter of rope.

Low Rate of Stretch.—The interior fibres do not destroy one another when bending over pulleys under strain.

The rope adapts itself to the groove and does not wear this out of shape. The one advantage Manilla rope possesses is the comparatively low first cost. This, however, is more than compensated for by the longer life, greater duty, and freedom from annoying delays which is given by the cotton rope.

The pulleys are usually of cast iron with their rims grooved; the grooves are generally made to an angle of 40 or 45 degrees for ropes about 1 inch diameter, and 30 degrees for ropes below 1 inch diameter; for thin bands running over very small pulleys more acute angles are usually adopted.

The width of pulley face, in inches, may be found approximately by multiplying the number of grooves by the pitch in inches, plus from 1 to 2 inches for thickness of outer flanges of outside grooves.

For a large mill engine as many as 80 ropes on the one fly-wheel are used, but 30 to 40 is a more common number

The following details are of fly-wheels recently constructed and erected, and may be said to represent the latest practice.

TABLE OF MODERN FLY WHEELS.

Hints for Planning out a Rope Drive.

It is often stated that 'the diameter of the pulleys should not be less than 30 times the rope diameter.' This is quite an empirical rule which has persisted since the early days of rope driving and which, with the moderate speeds and conditions prevailing up to a few years ago, served its purpose very well. The result of recent research, necessitated by the higher speeds and more difficult conditions of modern days, has shown that this rule is capable of very great modification, since the minimum advisable pulley diameter has been shown not to be a simple function of the rope diameter, but depends upon the following:

Rope speed; total tension on rope; actual diameter of rope.

The following table, extracted from a curve recently published by Messrs. Wm. Kenyon & Sons, Ltd., gives the result of their research on this subject.

TABLE OF ROPE SPEEDS.

(Wm. Kenyon & Sons, Ltd., Dunkinfield, Manchester.)

Speeds.	Minimum advisable Pulley Diameters in Inches.										
	¾ In.	⅞ In.	1 In.	1⅛ In.	1¼ In.	1⅜ In.	1½ In.	1⅝ In.	1¾ In.	1⅞ In.	2 Ins.
	Ins.	Ins.	Ins.	Ins.	Ins.	Ins.	Ins.	Ins.	Ins.	Ins.	Ins.
1,000 . .	10	12½	15	18½	20	24	28	31	35	40	45
1,500 . .	11½	14	16½	20	22	26	29	33	38	42	47
2,000 . .	12½	15	18	21½	24	28	31	35½	41	44½	50
2,500 . .	13½	16½	19½	23	26	30	34	38½	44	48	53½

7,000 . .	—	—	37	43	50	58	63	71½	79	88	96

The importance of large pulley diameter cannot be over-emphasised. The above table gives minimum pulley diameters for various sizes of rope at different speeds which are required to ensure a reasonable rope life with normal duty, but still larger pulleys mean a longer rope life, or, if required, higher duty.

Very short centre drives are not generally to be recommended, but if necessary there is no reason why they should not be perfectly satisfactory, provided precautions are taken in the design.

In the case of a drive where the pulleys are of unequal diameter, the portion of the pulley embraced by the ropes decreases with the distance between centres. This must be allowed for by increasing the number of ropes until the contact surface between the ropes and the smallest pulleys equals the usual standards. In other words, allow for the decreased arc of contact by increasing the number of contacts.

In all very short centre drives it is extremely unlikely that the ropes will ever have enough slack to allow of tightening by resplicing, though there might be enough slack to allow the ropes to slip. An allowance of 10 per cent. on the number of ropes decreases the load on each rope sufficiently to ensure that the above contingency will not arise.

Many short centre rope drives have been installed to replace gears, belts, etc., when the load is very erratic, and have proved to be the most economical method of transmitting power under these conditions.

Examples of this are :

(1) Rolling-mill gear-driven replaced by ropes, pulleys 4 ft. 3 ins. diameter, centres 6 ft., leaving rim clearance of 1 ft. 9 ins.
(2) 360 h.p. transmitted through pulleys with rims 8 ins. apart.

Long centres with ropes are, however, very much a matter of pulley diameters and direction of rotation, particularly on horizontal drives. When the lower side is the driving side, the centre distance is limited by the pulley diameters. The ultimate sag on the slack side seldom exceeds 7½ per cent., and 10 per cent. is ample for estimating the depth of a race or for clearing obstructions. Thus, presuming the use of pulleys each 10 ft. diameter, the centres may be extended to 100 ft. apart before the slack and tight sides touch each other, i.e. with the slack side uppermost. See fig. 7.

Reversing the direction of rotation, as per dotted lines on fig. 8, obviously permits of longer centres, reaching in several instances from 150 to 200 ft.

It is possible to extend centres to even greater distances than the above by the use of jockey pulleys, etc. ; but, generally speaking, it is far more economical to split the drive into two or more.

The following construction gives, closely enough for all practical purposes, the sag curve either above or below the pulleys :

With ' B ' as centre, fig. 7, p. 841, strike an arc with AD as radius ; with ' A ' as centre, strike an arc with BC as radius ; then the intersection is centre ' E ' for slack above.

With ' B ' as centre, strike an arc with BC as radius, with ' A ' as centre, strike an arc with AD as radius ; then the intersection is centre ' F ' for slack below.

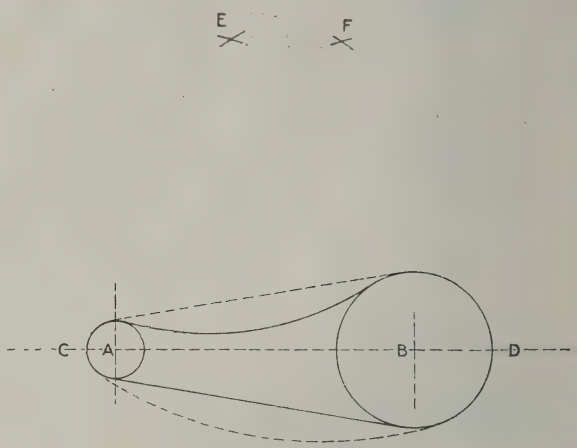

FIG. 7.—Sag of Rope.

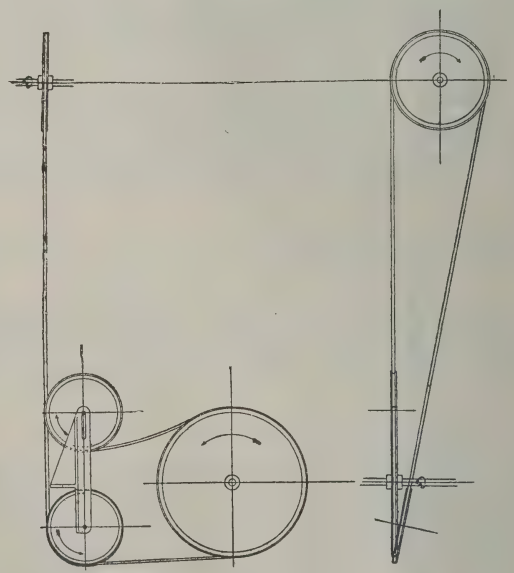

FIG. 8.

ROPE GUARD.

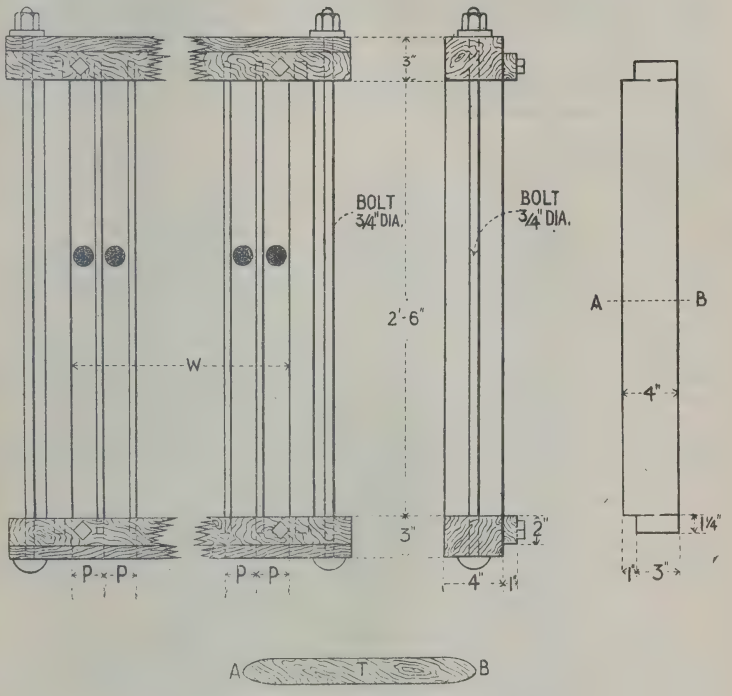

FIG. 9.

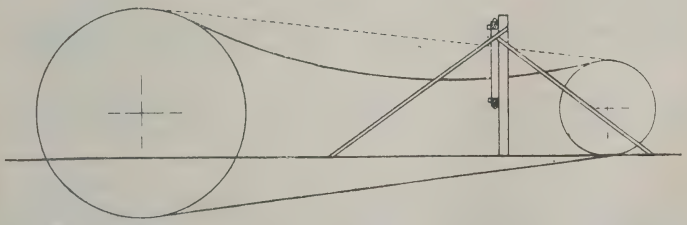

FIG. 10.

Drives with Irregular Impulses or Loads.

When either the load or impulse is irregular, there are two main effects which must be provided against. The first is, if the ropes are fully loaded, or nearly so, for the general conditions of the drive, the irregular load or impulse has the effect of causing the ropes to slip, although under a load equal to the average load, the drives might run perfectly well. In driving from single cylinder gas-engines (old type) as much as 50 per cent. extra ropes were sometimes found necessary. For a modern gas-engine 10 per cent. extra ropes are advisable.

The second is, that with either irregular impulses or loads, the ropes have a tendency to lash about, which, if not controlled, tends to excessive wear. The best thing to do is to regulate by flywheel effect and thus get rid of this action altogether. This, however, is not always possible. In that case the provision of a rope guard is advisable.

A design of the rope guard which has been used with great success is shown in fig. 9, p. 845, and the method of installation in fig. 10, p. 845.

To construct this, first determine the pitch, P, of the pulley grooves; let D = rope diameter; then thickness of blade $= P - \left(D + \frac{D}{8}\right)$.

The blades should be made of a good hard wood of even grain, without knots, with rounded edges, as shown on enlarged section. The ends are shaped to fit slots in cross-bars of frame, where they are held in place by stretchers secured with coach-screws, thus facilitating replacement in case of breakage.

The method of applying this rope guard depends upon the relative positions of the two pulleys and direction of rotation. In oblique driving it is often attached to the roof or sides of a building, stayed by iron rods and tilted to meet the driving angle. These thin wooden blades are quite sufficient to stop the largest ropes from lashing; the action of lashing being accumulative, the blades steady each small impulse as it arises.

For drives at right angles, whether for one or more ropes, the most satisfactory arrangement is shown in fig. 8, p. 844. The tight side of the rope is deflected by a guide pulley fixed at a suitable angle, while the slack side is directed by a pulley having its horizontal axis in line with the driven pulley. This arrangement is also suitable for shafts on the same plane.

Long keyways are advantageous in fixing up angular drives, as they enable the pulley to be moved to the most desirable position in the circumstances.

As the guide pulleys are not required to transmit power the grooves in the same, while being of the same pitch as those of the driver or driven pulleys, should be smooth and well rounded out, as shown in fig. 9 (p. 845).

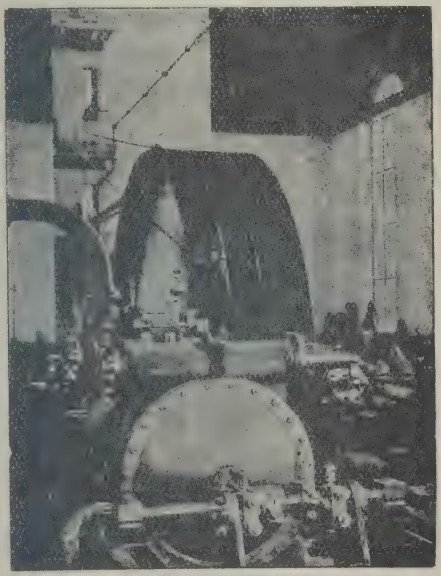
Crossed Rope Drives.

When power is transmitted by crossed ropes, between shafts rotating in opposite directions, there is unavoidable friction and wear at the point of crossing. These defects may be considerably reduced by arranging the tight side in each pair to run together in the centre and the slack side on the outside of these. If more than two ropes are employed, then sufficient empty groove spaces should be allowed between each pair so that they may pass without touching. Thus a pair of ropes would occupy two out of a set of three grooves the empty groove in the centre providing the clearance at the crossing.

The life on a good rope on a well-designed drive may be said to average ten years many cotton ropes are, however, running that have been working nearly three times this period.

Grooves.

When exact templates of existing grooves are required, the quickest and surest way is to take a plaster cast, the grooves having been previously well greased.



Flanged Grooves,

as shown by fig. 15 (p. 850), are very commonly used and are supposed to give direction to the ropes. Many engineers, however, prefer the flangeless groove as shown by fig. 12 (p. 847), and a groove angle of 40° instead of 45°. It is claimed that the more acute angle can transmit more power, and that it reduces the tendency of the rope to rotate, which action considerably reduces the life of the ropes.

Setting out a 40° groove.—A circle representing the required rope diameter is drawn, through which the vertical and horizontal centre lines are projected. The chord of the arc A B (see fig. 12) then becomes the standard of further measurements, decides the centre for the rounded base, and when doubled gives the point of intersection of the two sides. Continuing the sides above the horizontal line through the centre of the rope until they intersect, the horizontal line

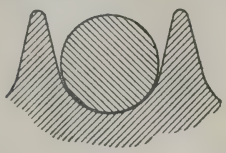

FIG. 11.—Form of groove for rope guide pulley.

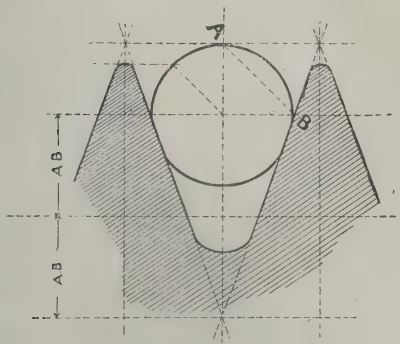

FIG. 12.—Flangeless groove with sides at 40°.

drawn tangential to the rope circumference at the point A gives the pitch. To obtain the top of the pulley, draw a line through the centre of the rope and parallel to the chord A B, and where this line intersects the rope circumference, draw a horizontal line to intersect the pitch line.

SIZES OF ROPES

The table of 'Minimum Advisable Pulley Diameters,' p. 843, gives useful information as to the most suitable size of rope for different sizes of pulleys, and it is intended to be used in conjunction with the 'Table of Powers for Cotton Ropes,' p. 849.

Power transmitted by Ropes.

Formerly, it was assumed that the h.p. which could be transmitted by the rope was dependent upon the total tension and on that alone, presuming that the pulley diameters were normal. This is shown graphically by fig. 13, where the straight diagonal line represents the power transmitted when centrifugal force is neglected, and the curve represents the h.p. when centrifugal force is taken into account and the total tension on the rope remains a constant.

This diagram has been constructed from the following data:

D = diameter of rope in inches; S = speed of rope in feet per second; T = total tension in lbs.; E = effective tension in lbs.; W = weight of one foot of rope in lbs. (The weight per foot is taken as ·27 D^2 lbs.); assume T to be 160 D^2. In order to obtain the effective tension (E) the loss due to centrifugal tension has to be deducted from the total stress.

$$\text{Centrifugal tension normal to a diameter in lbs.} = \frac{S^2 \times W}{32}.$$

The horse-power can now be calculated from the formula

$$\text{H.P.} = \frac{S \times E}{550}.$$

It can be seen from the diagram (fig. 13) that if the stress in the rope be increased, the maximum h.p. transmitted will be increased, and the speed at which this maximum h.p. occurs will be greater than 4,800 ft. per min. The effect of increasing the stress is to raise the curve of actual h.p. transmitted and cause the crown of the curve to be moved to the right of that shown in fig. 13.

It has been found in practice that a 1¼ in. diameter rope will transmit 72 h.p. at 7,200 f.p.m. without slip or excessive wear. This totally disagrees with the above conclusions which would give the power transmittible at certainly not more than 30 h.p.

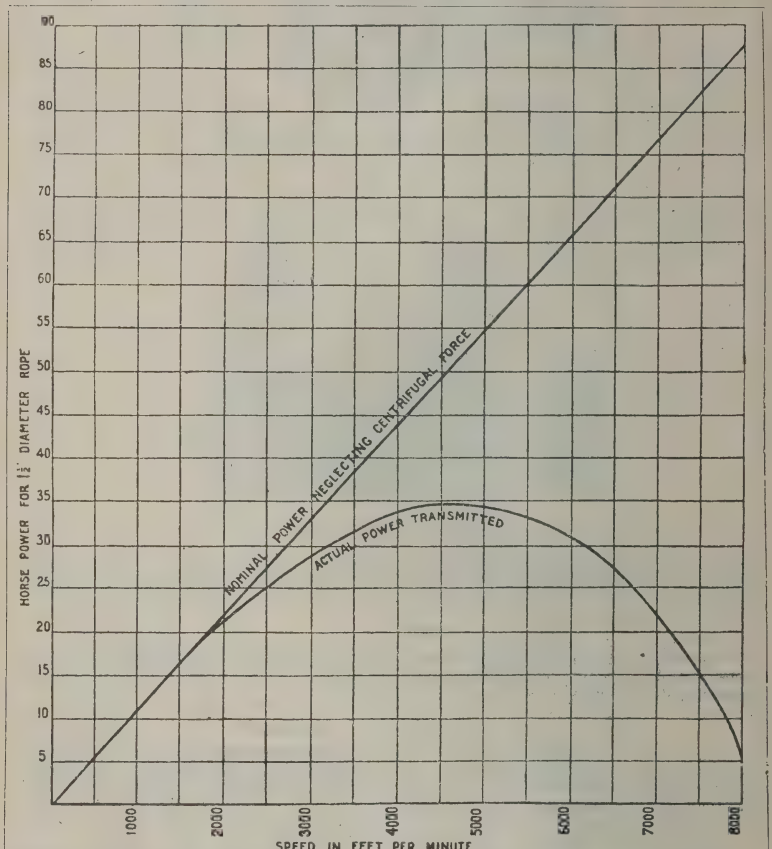

FIG. 13.—**Diagram showing the effect of Centrifugal Force at different speeds of rope.** For an available tension (T) in lbs. of 160 D^2 the best rope speed is shown to be about 4,800 feet per minute.

The explanation is, that wear—not total tension—is the limiting factor in any rope drive, provided there is sufficient arc of contact to prevent slip.

Wear is caused almost entirely by bending under strain, and varies with the total strain on the rope and the amount of bend. Thus, if the total strain is increased, then the amount of bend must be decreased—i.e. the pulley diameter increased.

It thus follows that all the conditions of each drive must be taken into consideration before stating what h.p. it will transmit with an average rope life.

A = Diameter of ropes.
B = Diameter of pulleys at 30 times the rope diameter.
C = Allowable reduction for small ropes.

Any increase in relative size of pulleys adds to the life of the ropes, particularly at velocities over 5,000 ft. per minute. Pulleys vary from 37 to 48 diameters at the high speeds mentioned.

(*E. Kenyon.*)

Efficiency of Rope Driving.

The conclusions deduced from a recent series of tests on the efficiency of rope driving are as follows:—The efficiency in rope driving is considerably greater at the lower speeds than at the higher ones, the dropping off being especially noticeable above 4,500 ft. per minute of rope speed.*

Flanged grooves (which are very commonly used) have not the same liability for the ropes to mount as the flangeless grooves have. The groove angle is usually 45°, but some engineers prefer the flangeless groove with an angle of 40°, claiming that the more acute angle can transmit more power.

The method of setting out Hart's improved rope groove is shown by figs. 14 and 15. One great advantage of this groove is that it is made so deep as to prevent the rope ever reaching the bottom, a very important point.

Construction for a 45° Rope Groove.

With centre O and radius OA, draw a circle equal in diameter to the rope required.
Draw horizontal and vertical diameters AOB and COD.
With A, B, and C as centres, and radius OA, draw arcs to intersect at P and Q.
Join P and Q to centre O, cutting circle at E and F.
Join DE and DF, and parallel to these two lines draw tangents to the circle cutting AB, produced at R and S.
Through R and S draw RT and SU parallel to COD, cutting PCQ, produced in T and U.
Make DG = DO and draw arc through G with radius = ½ OA.
Thickness of mid-feathers = ½ OA.
Round off all corners of the groove TRGSU.

* 'Times' Engineering Supplement, August 27, 1913; or 'Mechanical World,' August 29, 1913—'Efficiency of Rope Driving as a means of Power Transmission,' by Mr. E. H. Ahara.

The following *Hints to users of ropes* are taken from Mr. Thomas Hart's book on 'Rope Driving':—

Take care that ropes do not get wet; water does them much harm.

Take care that ropes do not rub on anything in their flight, either when running at full speed or when starting and stopping the engine.

Take care that ropes do not slip; if they slip they are probably overloaded, or are too small for the grooves.

All ropes should be lubricated with a good anti-fraying and lubricating composition. Black-lead mixtures should not be used.

Instructions for Splicing Lambeth Cotton Driving Ropes (Four Strand).

(*Thomas Hart, Ltd., Blackburn.*)

Storing, Stretching, etc.

If it is necessary to store the ropes before fixing, they should be kept in a dry room, not on an earthen floor. When ready for fixing uncoil the ropes left-handed—the opposite to the way the hands of a clock move. Then stretch out with a pair of hand blocks, but do not allow the rope to revolve during this operation, or the 'turn' or 'twist' will be taken out of it. Everything depends upon the strength of shafting, etc., as to how tight the rope should be stretched, but under ordinary circumstances it is usual to have about four men pulling on a pair of hand blocks. Pass a string around the drive to get the exact running length of rope, and by tying two bands around the rope, mark off the exact running length whilst it is on the stretch, allowing ten feet (five feet each end) for the splice. For ropes 2 ins. diameter allow 12 feet for splice.

Splicing.

Unlay the five feet each end that has been allowed for splice, that is, as far back as the bands which mark the running length of rope; it is advisable to tie a string around the end of each of the loose strands to prevent the twist from coming out. The strands are now interlaced together, one from the right-hand side being next to one from the left-hand side, and so on, as shown in fig. 16. These strands should be pulled tight so that the bands butt together, and

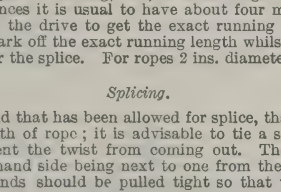

FIG. 16.

the loose strands on one side tied temporarily around the rope to keep the two ends of the rope in the position they now are.

Cut one of the bands, say the one on the right, and unlay strand No. 1A, at the same time laying in its place its fellow strand No. 1 from the opposite side of the rope. Do this for about four feet, and tie the two strands temporarily until all are ready for tucking in. The next strand to this, as will be seen in fig. 16, is numbered 2, but do not touch this now; take the next strand but one, numbered 3A, and unlay it, laying in its place strand No. 3, but only for about 1 ft. 6 ins.; tie these temporarily. It is very important in splicing four-strand ropes that two strands next to each other should not be laid up in the same direction.

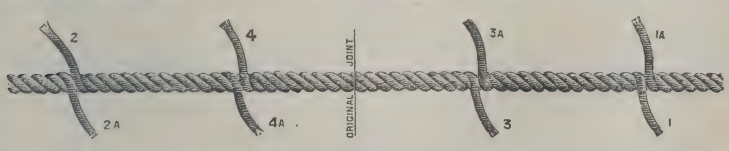

FIG. 17.

Next cut the other band, and proceed in the same manner with strands No. 2 and No. 4, but of course in the opposite direction. Care should be taken to keep the 'turn' or 'twist' in the strands, and they should be laid well and evenly down in their places. The splice should now be as fig. 17.

Begin now at joint No. 1 and 1A; untie the temporary fastening and shorten the strands to equal lengths of about 1 ft. 6 ins. An examination of the strands will show that the outside layer is composed of ten threads; for reference we will call these the friction bands; the internal portion of the strand we will call the tension strand. Take No. 1A and remove from it the ten friction bands and divide them into two lots of five, but do not cut them off. Now take strand No. 1 and unlay it two turns or laps, and whilst it is there remove from it the ten friction bands, divide them into two lots of five, but do not cut off. Now lay in again the tension strand only of No. 1 turn, and reduce it by leaving out about one-quarter, lay up the remaining three-quarters one turn, thus bringing it up to tension strand of No. 1A; tie the two with an overhand knot. At this knot the rope should be about its original diameter, and the joint should appear as shown in fig. 18.

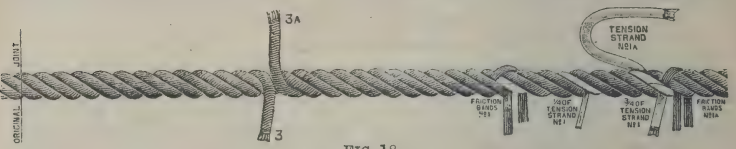

FIG. 18.

Take tension strand 1A and with the splicing pin work it under and over tension strand No. 1, as shown at fig. 19, passing it under and over spirally about five times; it will then have reached friction bands No. 1.

FIG. 19.

Now reduce it by cutting out a portion, and pass the remainder between the two lots of five friction bands, and lock by passing once or twice through the centre of the rope. This is clearly shown at fig. 20. Five friction bands are also locked through the rope as shown. This complete, turn to three-quarters of tension strand No. 1; this is locked exactly as tension strand No. 1A,

FIG. 20.

five of the friction bands are also locked as previously shown, and the splice should now be as fig. 20.

All loose ends are cut off and this portion is complete. Treat the two other joints in the same way and the splice is complete.

How to put a Rope on the Pulleys.

Put the rope on the small pulley, and as far around the large pulley as it will go; lash it there, but have the lashing so that the rope has freedom to slip through it. Then bar pulley slowly round by hand, or barring engine if there is one, and the rope will fall into its place. The groove of the small pulley and the face of the large pulley where the rope will touch in barring on should be well greased with tallow to prevent wedging. A piece of canvas may also be put on the rim of the large pulley to prevent it cutting the rope. (*Thomas Hart, Ltd.*)

Haulage Wire Ropes, Useful Sizes (Lang Lay).

Approximate Diameter.	Circumference of Rope.	Number of Strands.	Number of Wires in Strands.	Number of Wires in Core	Gauge of Wires.	Lay of Strands.	Lay of Rope.
Ins.	Ins.				In.	Ins.	Ins.
$\frac{5}{8}$	2	6	6	1	·072	$2\frac{1}{4}$	6
1	3	6	6	1	·105	3	$7\frac{1}{2}$
$1\frac{1}{4}$	4	6	8	7	·116	$3\frac{3}{4}$	9
2	6·2	6	10	7	·146	$4\frac{3}{4}$	13

In the 'Lang' Lay all the wires forming the strands, and the strands comprising the rope, are laid in the same direction. These ropes have been used for from 3 to 6 years hauling some 3,500,000 tons of coal, at speeds varying from 5 to 15 miles per hour, over distances up to 220,000 miles.

Blackett's Wire-Rope Socket.

Fig. 21 represents a section of Blackett's wire-rope socket. The cap or socket, A, made of iron or steel, and fitted with a lining, B, of some soft metal, is placed round the rope-end, C, which is brought into proper position, and then forcibly driven outwards against the lining, B, within the socket, the wire ends being held asunder by a tapered plug, D, made of soft metal similar to the

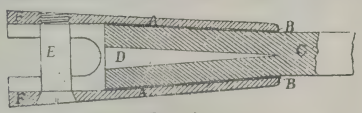

Fig. 21.

lining, B. A bolt, E, which serves to carry the load, or another socket, passes through a double eye. This arrangement forms a strong and compact job, and the process of socketing can be easily and rapidly performed.

Attaching ropes to joints or sockets by means of pins or rivets driven through the former is a detrimental, if not a dangerous, procedure.

Sizes of Pulleys and Drums.

The sizes of pulleys and drums should preferably be about ten times the circumference of the ropes to be used on the same, or, say, 1 foot in the diameter of the former for each pound of rope per fathom—e.g. a drum $3\frac{1}{2}$ feet in diameter for a rope weighing $3\frac{1}{2}$ lbs. per fathom.

LUBRICATION OF WIRE ROPE.

A very important detail in the lubrication of wire ropes is the application of the lubricant. On inclined and horizontal ropes, where operating speeds permit, operators very often pour the lubricant on the rope, the excess being caught in a pail, which serves the double purpose of container and overflow vessel. It has been found excellent practice to paint the lubricant on with a brush, catching the surplus, as before, in a pail. Good results have been obtained by providing each rope with a trough through which the rope is compelled to pass by making it run under a wheel mounted on the trough. Engineers report good service obtained by pouring the dressing on the winding drums. Others report that they have obtained best results by providing each rope with a split box of some 25 lb. capacity, into which compounds can be poured while hot, and through which the rope passes in operation. (*Lubrication.*)

CLUTCHES.

Friction Clutches.

Fig. 22 is one of the simplest forms of friction clutch. Part A clutches with part B (which is keyed to the shaft) by advancing the latter so that the conical surfaces are pressed together; these surfaces are sometimes covered with leather or fibre in order to increase the frictional resistance. When the members are mounted on separate shafts, it is generally advisable to mount

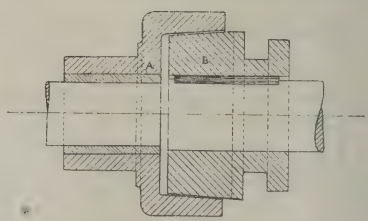

FIG. 22.

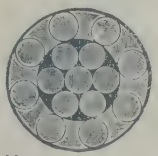

the sliding member on the driven shafts so that it may be at rest when not engaged. Where oil is likely to lodge between the two parts, small escape holes should be drilled parallel to the shaft axis through one of the members. These holes also allow of the escape of any air which may be trapped between the faces.

The Weston Friction Coupling.

This device is probably more frequently used as a brake than as a clutch, but is equally suitable for both purposes. In the design shown in fig. 23, the muff A is keyed to the shaft S, but can be moved along the same by means of a fork which fits into the groove at the right-hand end. This muff A is provided with several feathers F around its inside surface (or the inside surface

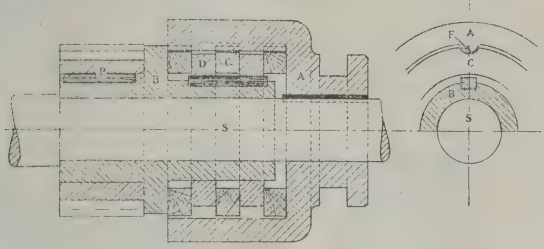

Fig. 23.

may be hexagonal), and into these are fitted the annular discs C. These discs are sometimes made of hard wood, but may be of iron. The member B, riding freely upon the shaft S, has a pinion P (or pulley) keyed to the outer end, and the metal rings D keyed to the sleeve. The rings D are free to move longitudinally along the sleeve, and are clear of the feathers F. Similarly the discs C are clear of the key in the sleeve B. On pressing A forward the axial force P is exerted on each of the rubbing faces and the frictional or turning effort increases with the number of rings.

The principle of the Benn and Hele-Shaw clutches is identical with the above.

The Hele-Shaw Clutch.

In this form of clutch, fig. 24 (for motor cars), all the plates have driving notches either on their outer or inner circumference. The outer plates, which are made of high-grade phosphor bronze, are driven by the engines, and the inner plates of mild steel drive the clutchshaft and so transmit the power to the gear-box. The clutch case, marked A, is bolted to the flywheel and so revolves with the engine. Around the inner side of this case there are teeth or feathers which engage with the notches in the outer (phosphor bronze) plates, so that these outer plates always revolve with the engine. Supported by a ball bearing on the end of the crankshaft is a steel core shown at B, which is connected with the clutch shaft C. This core, like the case, has driving teeth, but on the outer side, and these engage with the inner (steel) plates. There is a sleeve D sliding on the shaft and ending in a disc E, which presses the inner and outer plates together. This presser, as it is called, is normally kept tight against the plates by the pressure of the main clutch spring F, the other end of which is held by the spring adjusting cap G, screwed into the boss on the end of the case. In this way it is arranged that no thrust is exerted on the engine or the gear-box while the clutch is engaged. The spring adjuster is locked in position by the peg spring H, which can be raised out of engagement while the spring pressure is altered by screwing up the adjuster.

While the full spring pressure is keeping the outer and inner plates pressed together, the power of the engine will be transmitted to the gear-shaft.

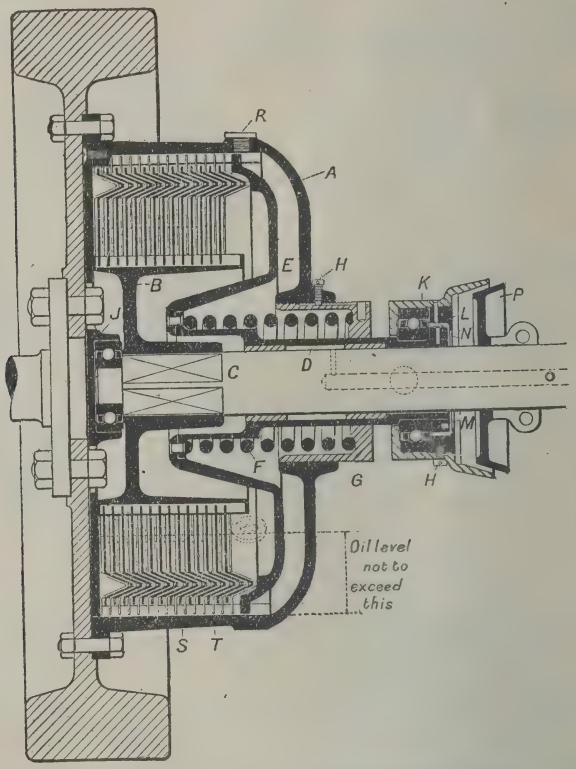
To disengage the clutch the presser is moved back by means of the actuator K, to take the pressure off the plates. This actuator has two pins engaging with the pedal levers below the foot pedal; the motion is transmitted to the presser through the ball-bearing and the lock nut M. This latter is prevented from slacking back by a simple locking device.

When the pressure has been taken off the plates, these might tend to stick together on account of the oil. To prevent this, the outer plates are fitted with small flat springs which are in compression when the clutch is engaged. When the presser slides back, the small springs throw the outer plates apart and make the clutch quite free. Occasional breakages of these springs having occurred after prolonged use, a new type of laminated spring, which is quicker in action and as durable as the plates themselves, is now being fitted.

In plate clutches of every form there is inevitably a slight drag, caused by the skin friction of the film of oil between the plates, which tends to keep the clutch shaft revolving when the clutch is out of gear. To mesh first speed or reverse, it is necessary that this shaft should be stopped; accordingly the actuator terminates in a cone which presses up against a corresponding coned part P revolving with the shaft. This constitutes a powerful clutch brake and frees even the largest size of clutch without difficulty. The coned brake piece is made adjustable to allow for wear of the plates.

When the clutch is let in slowly the slight friction caused by the oil between the plates tends to slowly start the car moving, and this starting effort increases till the whole of the spring pressure comes upon the plates. The oil is then forced out from between the surfaces and the plates come into close contact, forming a solid pack and transmitting the full power of the engine.

In practice it is found that the V-grooved twin plates are approximately three times as powerful as the same number of flat plates under the same pressure, and hence for the same work require but one-third of the spring pressure, or pedal pressure, to declutch. The plates being well separated right up to the point of work, and then only touching at the side of the V-grooves, free circulation of oil and extremely rapid dissipation of heat are ensured, so that the plates never burn the oil and may be engaged indefinitely without causing undue heat, whilst their working condition



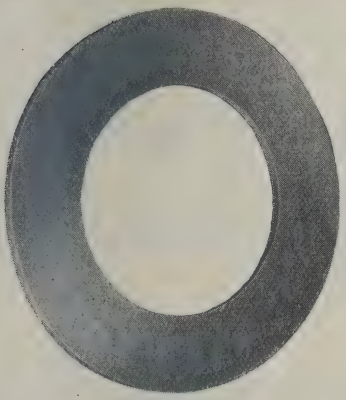


FIG. 24.—Sectional Elevation of the 'Hele-Shaw' Clutch bolted in position on Flywheel.

A, outer dust-proof case which forms oil bath; B, steel core; C, clutch shaft; D, actuating sleeve; E, presser; F, central control spring; G, adjusting nut; H, locking screws; J, retaining plate; K, actuator; L, external check nut; M, internal check nut; N, locking device; P, clutch brake; R, oil plugs; S, driven steel disc; T, driving bronze disc.

always remains constant. Further, in industrial work the clutch is capable of long-period slipping as part of its regular work. The V-groove in the twin plates adds so greatly to their transverse strength that buckling and distortion are impossible. Even under the most unfavourable working conditions, such as when through accidental loss of oil extreme heat is set up, the V-grooved plates still retain their shape.

The clutches are also made of a light type in which the outer case and liner with its teeth, also the presser, actuator, and other parts, are made by a patented process from pressed steel in place of being cast as in the standard patterns.

Rolling Mill
to
Motor Scooter

1. A Friction Clutch to transmit 300 H.P. for a Rolling Mill.

2. A Multi-Disc Clutch to transmit 1 H.P. for a Motor Scooter.

These are two of enquiries showing how widely diverse may be the application of Ferodo Friction Linings for the transmission of power.

Engineers will be interested in particulars of No. 1 The clutch was of the peripheral internal expanding type to transmit 300 H.P. at 8 r.p.m.—the torque being nearly 200,000 foot pounds, necessitating a pressure of 90 lbs. per square inch. Total pressure 80 TONS. We were able successfully to apply our Ferodo Linings for the very heavy duty required.

POSITIVE LOCK WASHER CO.,

20/24 JAMES WATT STREET, GLASGOW.

F. 857

The Benn Friction Clutch.

In this clutch (Type H), fig. 25, the friction plates move axially, practically bear against the entire faces of the drum, and are continuous. As a result of this construction the

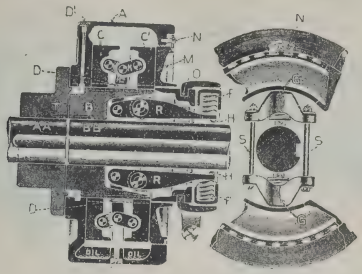

Fig. 25.

diameter, for a given power, is relatively small. As the movements of the plates are axial and not radial, they are unaffected by centrifugal force and the drum being relieved from bursting strains the clutch is suitable for high speeds. The lever stops H, as they approach, show at a glance the amount of wear and compensation, for this can be made by screwing in the plate M one or two notches. By screwing out the ring M and slacking back two set screws, the interior parts can be withdrawn without disturbing the shafts or parts keyed thereto.

The construction and action of the clutch is as follows :—

The boss T of drum A is keyed to the shaft AA, and the driving boss B to the shaft BB. On the driving boss B, the friction plates CC' are free to slide on feathers DD. These plates CC are connected by toggles KK, which, in turn, are connected by radial links LL to the levers RR. The ends of these levers RR carry compression springs FF, having their outer ends seated in the yokes GG. These yokes are connected to each other by the bolts SS, thus forming an equalising member, which absolutely *ensures uniform pressure* between all friction surfaces throughout the clutch. The cover M, forming one end of the drum, is accurately adjustable, and is notched to receive the lock plate N. The lever stops HH are to enable the position of the toggles KK to be ascertained from outside the drum.

The fig. shows the condition of the clutch when engaged, i.e., the plates bearing against M and A, the muff O in its inmost position, springs F in compression, the toggles KK in their most advantageous position (nearly straight), and the clutch locked by the radial link L being beyond the centre. On withdrawing the muff O the link L is pulled towards the right, the toggles KK are drawn towards the centre, and the plates C withdrawn from the drum faces.

The Johnson Friction Clutch.

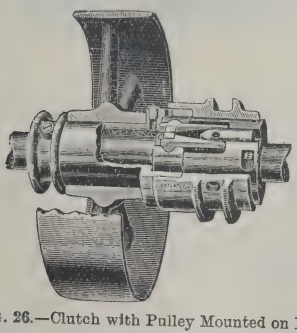

Fig. 26.—Clutch with Pulley Mounted on Hub.

This clutch, figs. 26, 27, consists of a body fastened to the shaft and carrying a split ring into which are inserted a pair of levers. A curved shaped wedge, which is made part of a sliding sleeve, forces the levers apart, expands the ring, bringing its outer surface into frictional contact

the driving plate lugs, whilst the other is free to be operated. A sliding member (*d*) is mounted on the shaft beyond the drum, its function being to pull the free end of the coil through a steel lever (*e*), which is pivoted on an extension of the driving place (*c*), and engages the free end of the coil.

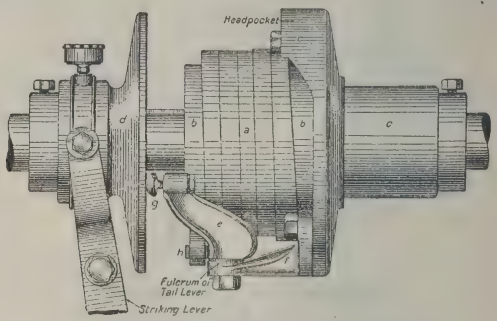

FIG. 30.

In engaging the clutch, the plate (*d*) is moved towards the drum, thereby tilting the lever (*e*) and tightening the free end of the coil, which is contracted and gradually tightens on to the drum (*b*), causing the different members of the clutch to be locked together. The action is similar to that of a man tightening the free end of a rope on a revolving capstan.

The clutch, made by the Coil Clutch Co. Ltd., Johnstone, is simple in construction and compact, and is used in colliery haulage gear, heavy cranes, and rolling mills.

Magnetic Clutches.

These consist of two members—the field or driving member, which carries the magnetising winding, and the armature, or driven member. In the design, by the Igranic Electric Co., shown in fig. 31, these members are carried on the face of annular spring steel plates attached to the

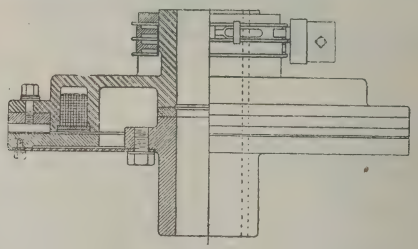

FIG. 31.

driving and driven hubs. Normally the members are held apart, but when the current is supplied to the windings of the field member they are magnetically drawn together, the flexibility of the spring steel plates allowing the necessary movement. The power is then transmitted entirely by the friction. The engaging surface, fitted externally to the poles of the field member, is composed of woven asbestos and brass wire, and stands proud of the pole faces so as to prevent these coming into contact with the armature. This type of clutch can pick up the load gradually, and can be controlled from remote positions.

In selecting a clutch, attention must be given to the starting torque required in overcoming the inertia of the part, means of stopping quickly in case of accident, and the effect of centrifugal forces on engaging parts in retarding their release or in throwing the members out of action.

Friction Surfaces.

In friction clutches the mating surfaces are sometimes of special materials in order to increase the grip. These materials are usually secured to the body of the clutch by pins, and trouble occasionally arises through the pins shearing. Preferably the fabric should be secured to the body with brass bolts. For low speeds and light pressures wooden surfaces are very suitable, but under opposite conditions the wood becomes charred. When the mating surfaces are of steel one of these should be casehardened. Steel should not be used with cast iron unless the latter has been chilled. In general close grained cast iron on cast iron gives the best results. A soft material should not be used with a metal which tends to crumble, as hard particles of the latter get imbedded in the former, and severe scoring results.

(*Dempster Smith.*)

Ferodo Friction Linings.

Description.

Ferodo Friction Linings (*Ferodo Ltd.*) are fabrics of distinct forms, i.e. fibre cotton base, and bonded asbestos, the object and use of each being to provide a surface which in rubbing contact with metal gives a high coefficient of friction which rises with the temperature and is not physically affected by the presence of oil or water—in fact, a damp or greasy surface improves the durability of Ferodo friction linings, but decreases their frictional value in proportion to the quantity and nature of the lubricant present.

Tests.

Tests on Ferodo fibre prove the average coefficient of friction to be 0·5; the maximum obtained being 0·7—the temperature limit for the fabric being about 400° F.; the material has great mechanical strength and wearing qualities.

Tests on Ferodo bonded asbestos prove the average coefficient of friction to be 0·3 and that the efficiency of the fabric is maintained at any temperature up to 500° F. (260° C.).

Clutches.

Ferodo fabric forms a clutch lining which does not *seize* and which allows a gentle engagement even when the surfaces are greasy or wet. In the case of a cone clutch lined with Ferodo fabric, included angles of 24° to 34° are recommended, owing to the high coefficient of friction.

For flat-plate clutches, Ferodo friction linings are made up in the form of circular discs, made either jointless or with a butt joint stitched with fine soft metal wire.

SECTION XVIII

PART II

CHAIN GEARING.

(Association of British Driving Chain Manufacturers.)

The adaptability and high efficiency of chain gearing for the transmission of power is now extensively recognised. Although the advantages of chain driving are not yet fully appreciated, the attention of power users and engineers when considering methods of transmission should be directed towards embodying chain drives of suitable type.

Although belts, ropes, and the several forms of toothed wheel gearing will always have their place, chain drives can in many cases be employed with greater advantage. Chain gearing ensures a positive transmission, at the same time affording a beneficial measure of elasticity. The efficiency of a well-designed chain drive is very high, the loss of power in many cases not exceeding 2 per cent. throughout the useful life of the chain and wheels. Thus, chain gearing has a higher maintained efficiency than any other form of transmission.

The initial tension required with a belt is unnecessary with a chain, and the bearing friction due to it is therefore eliminated.

Chain drives can be used under very varying conditions in respect of:—(*a*) Speed ratios, which can be readily modified; (*b*) centres of shafts. Chain gearing can be used at centres which are too long for spur gears and too short for belts or ropes; (*c*) nature of the load; (*d*) temperature; (*e*) humidity; (*f*) power to be transmitted.

TYPES OF CHAINS.

The two general types of power transmission chains are shown by figs. 1 and 2. Speaking generally the Inverted Tooth type is used for high-speed drives, and the Bush Roller type for medium and low speeds.

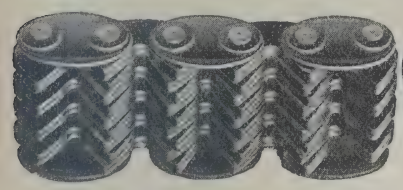

FIG. 1.—Inverted Tooth Type.
(Known as Silent or Noiseless.)

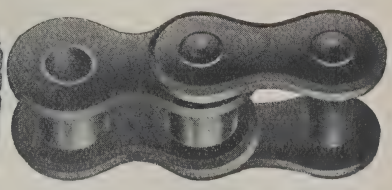

FIG. 2.—Roller Type.

DESIRABLE CONDITIONS FOR APPLICATION OF CHAIN GEARING.

The following statement, prepared by the Association of British Driving Chain Manufacturers, shows the approximate limits that usually obtain in the economical application of chain gearing. Where circumstances do not permit its application within these limits, the chain manufacturer should be consulted.

GEAR RATIO (maximum): Roller Type, 7 : 1; Inverted Tooth Type, 6 : 1.

Chain Speed.

Normal maximum, assuming the number of teeth is 19 for roller type and 21 for inverted tooth type :—

Pitch.	Roller type feet per min.	Inverted tooth type feet per min.
Up to ½ in. pitch	1,000	1,500
⅝ in. and ¾ in. „	900	1,400
1 in. and 1¼ in. „	800	1,350
1½ in. and 1¾ in. „	700	1,300
2 in. and 2½ in. „	600	1,250
3 in. „	500	1,200

Number of Teeth in Wheels.

Minimum	Roller type	17	Inverted tooth type	19
Maximum	„	120	„ „ „	120 *

In cases where the chain speed is substantially less than that shown above, for any given pitch, the number of teeth in the pinion may be reduced.

Centre Distance between Shafts.

The maximum centre distance between chain wheels is governed by so many considerations, such as inclination, nature of load, size of wheel, etc., that it is difficult to lay down any general rule. The following limiting values for ordinary conditions and steady loads are therefore liable to considerable variation in individual circumstances.

(*a*) *Desirable Maximum Centre Distance.*

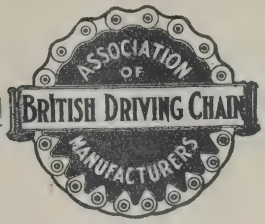
(Expressed in Pitches of Chain.)

Pitch of Chain.	Type of Chain.	
	Roller.	Inverted Tooth.
⅜ in. to ¾ in.	100	70
1 in. to 1¾ in.	85	60
2 ins. upwards	70	50

With inclined drives with the wheel higher than the pinion, and with an inclination up to 60°, the horizontal component of the actual centre distance should not exceed the foregoing values.

In the case of vertical drives, and those with an inclination approaching the vertical, the chain manufacturers should be consulted.

(*b*) *Desirable Minimum.*—The centre distance should be such that the arc of contact between the chain and any wheel is not less than 120°, and with at least 7 teeth in engagement.



(*c*) *Adjustment.*—It is advisable to provide suitable means for the adjustment of the centre distance, and the normal minimum amount of this adjustment should be 1½ times the pitch of the chain.

In some cases adjustment can only be obtained by the use of a jockey wheel, which must engage with the slack side of the chain and have machine-cut teeth.

(*d*) *Chain Length.*—It is desirable that the number of pitches in the chain should not be a multiple of the number of the teeth in either the pinion or the wheel.

---

* This applies only to inverted tooth chains with a profile based on a 60° link face angle.

CHAIN GEARING

NO other form of power transmission maintains such a high standard of efficiency as Chain Gearing. Whilst positive in its action, chain gearing affords a beneficial measure of elasticity, and is operative without the initial tension that is required for belts, thereby reducing bearing friction to a minimum.

The adaptability, durability, reasonable initial cost, and maintained efficiency makes chain gearing the ideal transmission for power users.

Enquiries for Chains, Wheels and Cutters, should be submitted to the individual members of the Association. (See Overleaf.)

ASSOCIATION OF
BRITISH DRIVING CHAIN
MANUFACTURERS.
Bassishaw House, Basinghall Street, London, E.C. 2.

Disposition of Drives and Direction of Rotation.

Drives may be arranged to run horizontally, inclined, or vertical.

In the case of an inclined drive with the pinion on top, the maximum angle of inclination should approximate 45° from the horizontal.

In cases where the inclination of the drive exceeds 45°, the large wheel should preferably be on top.

In the case of vertical drives adjustment must be provided and carefully attended to.

The direction of rotation should be such that the tight or driving side of the chain is on top.

Clearance.

(In Inches.)

The minimum radius of clearance for that portion of the chain which is in contact with the wheels should be

$$\frac{\text{Pitch diameter} + 3\ (\text{pitch})}{2}.$$

The clearance for sag should be greatest at a point somewhere midway along the free portions of the chain, and this clearance should be allowed for both above and below each free portion of chain.

The minimum amount of clearance is

$$\frac{\text{Centre distance between wheels (in inches)}}{12} + \tfrac{1}{4}\text{ in.}$$

The total amount of side clearance for any chain drive may be found by the following formula:

$$\frac{\text{Centres of wheels (in inches)}}{30} + \frac{1}{2 \times \text{width of chain (in inches)}}.$$

This total amount of clearance should in general be equally divided on either side of the chain.

Lubrication.

Lubrication of the working joints is essential for chain gearing.

The most efficient form of lubrication is to enclose the drive in a case and pump a constant stream of oil on to the inside faces of the chain from a filter sump. An alternative arrangement is to run the chain through oil. Where the pinion is below, and is too small to allow the chain to run through oil, an oil thrower disc of a larger diameter than the pinion may be utilised.

For speeds up to 1,000 feet per minute a drip-feed lubricator may be used, fixed so that the oil drips regularly on to the inner face of the chain. A light or medium machine oil should be used, and one drip pipe provided for every 3 in. of chain width. A splash guard or case may be necessary for this method of lubrication.

For slow-running chains up to 500 feet per minute satisfactory lubrication can be obtained by removing the chain periodically, and, after thoroughly cleansing with paraffin, immersing it in a bath of warm mineral oil or grease for such a time as to allow the lubricant to penetrate to the rivets.

Chain gearing should not be unduly exposed to damp or dirt.

Sternol Chain Grease.

(*Sterns, Ltd.*).

This is a new grease recently put on the market to suit marine chain drives. It is claimed to be greatly superior to greases manufactured on a graphite basis.

Erection.

Chain wheels must be rigidly mounted on shafts which are parallel and truly horizontal, and the teeth of the wheels must be in correct alignment.

Where possible, wheels should be placed close to bearings, and must run true on their shafts.

Care should be taken that the chain connection is properly secured.

Before starting up the drive the chain should be adjusted to the correct tension and lubricated.

Maintenance.

Periodic examination is advisable to ascertain:

(*a*) If correct alignment of the wheels has been maintained; (*b*) if undue wear is taking place; (*c*) if adjustment of chain tension is needed; (*d*) if the chain requires cleaning; (*e*) if lubrication is being effectively carried out.

Improved service usually results when chains are removed from time to time for cleaning. They should be washed with paraffin and, after draining, thoroughly lubricated before being again used.

When fitting new chains, always ascertain that undue wear has not taken place on the teeth of the wheels.

The Association Standards for Roller Type Chains.

The Association has effected the standardisation of roller chains and wheel-tooth widths as used for power transmission generally. The Association Standards are as follows :—

Roller Type up to ¾ in. pitch.

Association Chain No.		Pitch.	Max. Roller Dia.	Min. Width between Plates.		Min. Depth of Shroud below Roller Seating.	Max. Tooth Width.	
Narrow.	Wide.			Narrow	Wide.		Narrow.	Wide.
		In.	In.	In.	In.	In.	In.	In.
3 N	3 W	⅜	0·250	0·155	0·230	0·070	0·145	0·220
Cycle Sizes.		½	0·305	0·130	0·192	0·050	0·120	0·182
4 N	4 W	½	0·335	0·205	0·305	0·094	0·195	0·295
5 N	5 W	⅝	0·400	0·255	0·380	0·117	0·245	0·370

Cutter Forms for Roller Type Chains.

For the convenience of chain users and to ensure complete interchangeability, the Association has standardised tooth forms which, while not being identical with any of the existing forms,

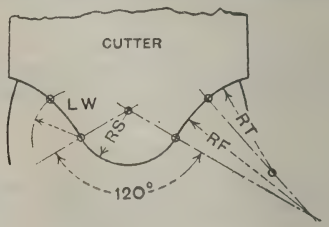

Fig. 3.

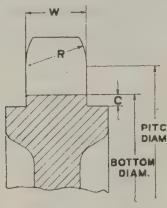
incorporates the essential features of each. The general construction is shown in fig. 3. It consists of a *roller seating*, *working faces*, and *topping curves*, all of which are arcs of circles.

The angle of 120° subtending the roller seating has its origin at the centre of the diameter of the roller seating. The working faces are comparatively flat curves tangential to the roller seating, and the topping curves are tangential to the working faces and of such a radius as to give a suitable height of tooth. The dimensions of tooth forms for the Association Standard Chains are given in the following table:



Roller Diameter.	Cutter No.	No. of Teeth to Cut.	Length of Working Face. L.W.	Radius of Roller Seating. R.S.	Radius of Working Face. R.F.	Radius at Top of Tooth. R.T.
Ins.			In.	In.	Ins.	Ins.

WHEELS.

It is of the utmost importance that chain wheels should have their teeth accurately machined with cutters of correct form. Pinions should preferably have an odd number of teeth to equalise wear on the chain.

(*a*) *Section Profile of Teeth for Roller Chains.*—Chain wheel blanks should be machined as indicated in fig. 4.

ASSOCIATION TOOTH PROFILE
FOR STANDARD ROLLER CHAINS

W = Width between inside plates minus 0·02 pitch.

R = Roller diameter.

$C = \frac{3 \times \text{pitch}}{16}$

Bottom diam. = Pitch diam. minus max. roller diam.

FIG. 4.

(*b*) *Pitch Diameters.*—The following table gives correct pitch diameters for all types of chain having a pitch of 1 in. The pitch diameters for wheels to suit other pitches of chain are directly proportional to the pitch of the chain.

No. of Teeth.	Pitch Diam.	No. of Teeth.	Pitch Diam.	No. of Teeth.	Pitch Diam.	No. of Teeth.	Pitch Diam.	No. of Teeth.	Pitch Diam.	No. of Teeth.	Pitch Diam.
9	2·924	24	7·661	39	12·428	55	17·517	71	22·607	86	27·381
10	3·236	25	7·979	40	12·746	56	17·835	72	22·926	87	27·699

18	5·759	33	10·520	48	15·290	64	20·380	80	25·471	95	30·245
19	6·076	34	10·838	49	15·608	65	20·698	81	25·790	96	30·563
20	6·392	35	11·156	50	15·926	66	21·016	82	26·108	97	30·881
21	6·710	36	11·474	51	16·244	67	21·335	83	26·426	98	31·200
22	7·027	37	11·792	52	16·562	68	21·653	84	26·744	99	31·518
23	7·344	38	12·110	53	16·880	69	21·971	85	27·063	100	31·836
				54	17·198	70	22·289				

(*c*) *Limits of Accuracy for Cutting.*—The tolerance for the bottom diameter of the tooth gaps may be 0·1 per cent. of the number of inches of the pitch diameter, but in any case, shall be within the following limits:

Minimum tolerance, 0·005 in.; maximum tolerance, 0·020 in.

The foregoing only deals with normal practice and relatively steady loads. Chain gearing is being used satisfactorily under conditions outside those here defined. Inquiries relative to special drives, impulsive loads, or any abnormal conditions, should be referred to the chain manufacturers.

THE WESTINGHOUSE MORSE ROCKER-JOINT CHAIN.

(*The Westinghouse Morse Chain Co. Ltd.*)

These chains, fig 5, form an important departure in silent chain driving Until their introduction the principal objection to chains was found in the rapid wear and consequent stretch. This is necessarily present with all chains having round joint-pins, friction due to sliding surfaces being unavoidable. A very ingenious feature is the joint, which consists of two pieces, fig. 7,

i.e. the rocker and seatpin, the former being provided with a knife edge which rocks on the face of the latter when the joint passes on or off the wheel. The bearing surface extends throughout the width of the chain. The pins for all practical purposes are an integral part of the link, fig. 6,

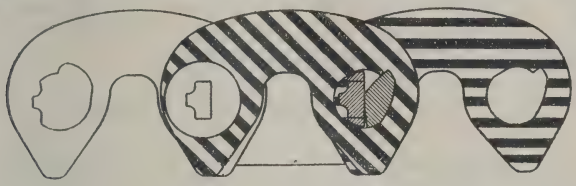

FIG. 5.

hence the only motion which takes place at the joint is a rocking movement. This ensures absence of sliding friction, which means the reduction of wear at the joint to the minimum, with consequent maximum life and efficiency. The shape of the tooth permits silent running, even under high speed.

Another important departure in the Westinghouse Morse chain drive is that represented by the No. 25 reinforced type chain—shown in fig. 8. In this construction the outer links are all knit together by short rivets and spacing pieces, adding very considerably to the material strength of the chain; also distributing the load more equally, and enabling the chain to run at higher speeds than has hitherto been possible.

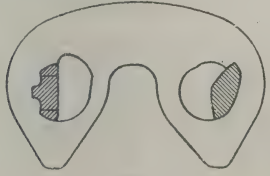

FIG. 6.

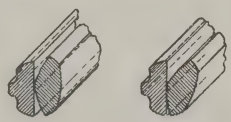

FIG. 7.

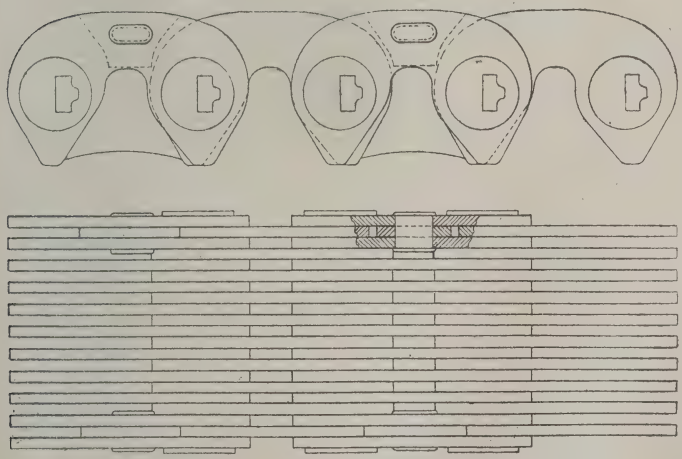

FIG. 8.

The greatest ratio of gearing under favourable conditions with the Westinghouse chains is 10 : 1. The following table gives the various pitches manufactured and the maximum permissible R.P.M. (revolutions per minute) for each:

Max. R.P.M.	2,000	1,600	1,400	1,100	1,000	800	700	600	400	250
Pitch in ins.	½	⅝	¾	·9	1	1·2	1·25	1·5	2	3

The chain width depends on the speed, determined as follows :—

$$\text{Speed} = \frac{N \times P \times \text{R.P.M.}}{12} = \text{F.P.M.} \qquad \text{Load} = \frac{\text{H.P.} \times 33{,}000}{\text{F.P.M.}} = \text{total load on chain in lbs.}$$

where

H.P. = Maximum horse-power ; P. = Circular pitch in inches ;
N = No. of teeth ; F.P.M. = Feet per minute.

This total load divided by the load per inch width advised gives the width of the chain.

Average permissible loads per inch in width for general machine-shop drives are as follows :—

Lbs. per inch wide	65	80	95	120	135	160	190	220	350	600
Pitch in ins.	½	⅝	¾	·9	1	1·2	1·25	1·5	2	3

Good chain speeds for average machine-shop drives are from 1,200 to 1,500 ft. per min.

As no friction due to sliding surfaces takes place, however, Westinghouse chains can be run at speeds which would, owing to centrifugal force, throw off all lubricant, and drives of this make are now transmitting light loads satisfactorily at 3,000 ft. per min. chain speed.

In view of its special joint construction, the Westinghouse Morse rocker-joint chain is claimed to surpass all others in point of size and strength, and the fact of being able to manufacture so large a size of silent chain as the 3-in. pitch in widths up to 24 ins. has resulted in such chain drives being applied for transmissions up to even 5,000 h.p. in a single drive.

The Westinghouse Morse chains are made in nineteen different types and pitches by the Westinghouse Morse Chain Co. Ltd., The Chaineries, Letchworth, Herts, and single drives can be furnished for transmitting from ¼ h.p. up to 1,000 h.p.

SECTION XVIII

PART III

TOOTH GEARING.

The word 'diameter,' when applied to gears, is always understood to mean the pitch diameter.

Diametral pitch of the gear is the number of teeth to each inch of its pitch diameter.

If a gear has 40 teeth and the pitch diameter is 4 ins., there are ten teeth to each inch of the pitch diameter, and the diametral pitch is 10, or in other words, the gear is 10 diametral pitch.

Circular pitch is the distance from the centre of one tooth to the centre of the next tooth, measured along the pitch circle.

If the distance from the centre of one tooth to the centre of next tooth, measured along the pitch circle, is $\frac{1}{2}$ in., the gear is $\frac{1}{2}$ in. circular pitch.

The diametral pitch given, to obtain the circular pitch divide 3·1416 by the diametral pitch.

If the diametral pitch is 4, divide 3·1416 by 4, and the quotient, ·7854 in., is the circular pitch.

The circular pitch given, to obtain the diametral pitch divide 3·1416 by the circular pitch.

If the circular pitch is 2 ins., divide 3·1416 by 2, and the quotient, 1·5708, is the diametral pitch.

The number of teeth and the diametral pitch given, to obtain the pitch diameter divide the number of teeth by the diametral pitch.

If the number of teeth is 40, and the diametral pitch 4, divide 40 by 4, and the quotient, 10, is the pitch diameter.

The number of teeth and the diametral pitch given, to obtain the whole diameter or size of blank of gear, add 2 to the number of teeth and divide by the diametral pitch.

If the number of teeth is 40, and the diametral pitch is 4, add 2 to the 40, making 42, and divide by 4 ; the quotient, $10\frac{1}{2}$, is the whole (or outside) diameter of the gear or blank.

The number of teeth and the diameter of the blank given, to obtain the diametral pitch add 2 to the number of teeth and divide by the diameter of the blank.

If the number of teeth is 40 the diameter of the blank is $10\frac{1}{2}$ ins., add 2 to the number of teeth, making 42, and divide by $10\frac{1}{2}$; the quotient, 4, is the diametral pitch.

The pitch diameter and the diametral pitch given, to obtain the number of teeth multiply the pitch diameter by the diametral pitch.

If the diameter of the pitch circle is 10 ins., and the diametral pitch is 4, multiply 10 by 4 and the product, 40, will be the number of teeth in the gear.

The whole diameter of the blank and the diametral pitch given, to obtain the number of teeth of the gear multiply the diameter by the diametral pitch and subtract 2.

If the whole diameter is $10\frac{1}{2}$ and the diametral pitch is 4, multiply $10\frac{1}{2}$ by 4, and the product, 42 less 2, or 40, is the number of teeth.

The thickness of a tooth at the pitch line is found by dividing the circular pitch by 2, or divide 1·57 by the diametral pitch.

If the circular pitch is 1·047 inch, or the diametral pitch is 3, divide 1·047 by 2, or 1·57 by 3, and the quotient, ·523 inch, is the thickness of tooth.

The whole depth of a tooth is found by dividing 2·157 by the diametral pitch.

If the diametral pitch of a gear is 6, the whole depth is 2·157 divided by 6, equals ·3595.

The whole depth of a tooth is about $\frac{11}{10}$, or exactly ·6866 of the circular pitch.

If the circular pitch is 2, the whole depth of tooth is about $1\frac{1}{10}$ of 2 ins., or $1\frac{3}{8}$ in. nearly.

The distance between the centres of two gears is found by adding the number of teeth together, and dividing half the sum by the diametral pitch.

If two gears have 50 and 30 teeth respectively, and are 5 pitch, add 50 and 30, making 80, divide by 2, and then divide the quotient, 40, by the diametral pitch, 5, and the result, 8 ins., is the centre distance. (*Brown and Sharpe.*)

The foregoing definition of the *diametral pitch*, which may also be expressed as the number of teeth in the wheel divided by the pitch circle diameter, is very commonly used. Others again understand the diametral pitch to be the reciprocal of the above, viz. pitch circle diameter divided by the number of teeth, and this definition appears to be the most logical one. Where the latter definition is used, the quantity, 'number of teeth divided by the diameter,' is known as the 'pitch number,' and is written, '4's pitch,' or '5's pitch,' as the case may be.

On the continent of Europe the 'Module' is commonly adopted. All dimensions are in millimetres, and the module is the addendum or the pitch diameter in millimetres divided by the

number of teeth in the wheel. The pitch diameter is the module multiplied by the number of teeth in the wheel.

Pitch Line or Circle.—The circle upon which the pitch is measured, and the circumference by which the diameter, or the velocity of the wheel, is measured.

Chordal Pitch.—A straight line drawn from the centres of two contiguous teeth upon the pitch line.

Line of Centres.—The line between the centres of two wheels.

Radius of a wheel.—The semi-diameter running to the periphery of a tooth.

Pitch Radius.—The semi-diameter running to the pitch line.

Length of a Tooth.—The distance from its base to its extremity.

Depth of a Tooth.—The distance from face to face, measured at the pitch line.

Breadth of a Tooth.—The distance between the sides.

A Trundle, Lantern, or Wallover—that is, a pinion constructed of round bars or solid cylinders set in two discs—can be operated uniformly by a wheel with any number of teeth, but must have at least 8 staves.

The number of teeth in each pinion should preferably be to the number of teeth in its wheel as 1 : 3·59, and the ratio should never exceed 1 : 6.

When a *Pinion is driven by a wheel*, the number of teeth in the pinion should not be less than 8.

When a *Wheel is driven by a pinion*, the number of teeth in the pinion should not be less than 10.

The *Number of Teeth* in a cast wheel, particularly in mill gearing, should always be prime to the number of the pinion ; that is, the number of teeth in the wheel should not be divisible by the number of teeth in the pinion without a remainder. This is in order to prevent the same teeth coming together so often as to cause an irregular wear on the same. An odd tooth introduced into a wheel is termed a *hunting tooth* or *cog*.

To compute the Pitch of a Wheel.

RULE.—Divide circumference at the pitch line by the number of teeth.

EXAMPLE.—A wheel 40 ins. in diameter requires 75 teeth ; what is its pitch ?

$$\frac{3{\cdot}1416 \times 40}{75} = 1{\cdot}6755 \text{ ins.}$$

To compute the Chordal Pitch.

RULE.—Divide 180° by the number of teeth, ascertain the sine of the quotient, and multiply it by the diameter of the wheel.

EXAMPLE.—The number of teeth is 75, and the diameter 40 ins. ; what is the chordal pitch ?

$$\frac{180}{75} = 2° \; 24' \text{ and sine of } 2° \; 24' = {\cdot}04188, \text{ which} \times 40 = 1{\cdot}6752 \text{ in.}$$

To compute the Diameter of a Wheel.

RULE.—Multiply the number of teeth by the pitch, and divide the product by 3·1416.

EXAMPLE.—The number of teeth in a wheel is 75, and the pitch 1·675 inches ; what is the diameter of the wheel ?

$$\frac{75 \times 1{\cdot}675}{3{\cdot}1416} = 40 \text{ inches.}$$

To compute the Number of Teeth in a Wheel.

RULE.—Divide the circumference by the pitch.

To compute the Diameter when the True Pitch is given.

RULE.—Multiply the number of teeth in the wheel by the true pitch, and again by ·3184.

EXAMPLE.—Taking the elements of the last example,

$$75 \times 1{\cdot}675 \times {\cdot}3184 = 40 \text{ inches.}$$

To compute the Number of Teeth in a Pinion or Follower to have a given Velocity.

RULE.—Multiply the velocity of the driver by its number of teeth, and divide the product by the velocity of the follower.

EXAMPLE 1.- The velocity of a driver is 16 revolutions, the number of its teeth, 54, and the velocity of the pinion, 48 ; what is the number of its teeth ?

$$\frac{16 \times 54}{48} = 18 \text{ teeth.}$$

EXAMPLE 2.—A wheel having 75 teeth is making 16 revolutions per minute; what is the number of teeth required in the pinion to make 24 revolutions in the same time?

$$\frac{16 \times 75}{24} = 50 \text{ teeth.}$$

To compute the Proportional Radius of a Wheel or Pinion.

RULE.—Multiply the length of the line of centres by the number of teeth in the wheel for the wheel, and in the pinion for the pinion, and divide by the number of teeth in both the wheel and pinion.

To compute the Diameter of a Pinion when the Diameter of the Wheel and Number of Teeth in the Wheel and Pinion are given.

RULE.—Multiply the diameter of the wheel by the number of teeth in the pinion, and divide the product by the number of teeth in the wheel.

EXAMPLE.—The diameter of a wheel is 25 inches, the number of its teeth 210, and the number of teeth in the pinion 30; what is the diameter of the pinion?

$$\frac{25 \times 30}{210} = 3{\cdot}57 \text{ inches.}$$

To compute the Number of Teeth required in a Train of Wheels to produce a given Velocity.

RULE.—Multiply the number of teeth in the driver by its number of revolutions, and divide the product by the number of revolutions of each pinion, for each driver and pinion.

EXAMPLE.—If a driver in a train of 3 wheels has 90 teeth, and makes 2 revolutions, and the velocities required are 2, 10, and 18, what are the number of teeth in each of the other two?

$$10 : 90 :: 2 : 18 = \text{teeth in 2nd wheel.}$$
$$18 : 90 :: 2 : 10 = \text{teeth in 3rd wheel.}$$

To compute the Circumference of a Wheel.

RULE.—Multiply the number of teeth by their pitch.

To compute the Revolutions of a Wheel or Pinion.

RULE.—Multiply the diameter or circumference of the wheel, or the number of its teeth, as the case may be, by the number of its revolutions, and divide the product by the diameter or circumference of the wheel, or number of teeth in the pinion.

EXAMPLE.—A pinion 10 inches in diameter is driven by a wheel, 2 feet (24 inches) in diameter, making 46 revolutions per minute; what is the number of revolutions of the pinion?

$$\frac{24 \times 46}{10} = 110{\cdot}4 \text{ revolutions.}$$

To compute the Velocity of a Pinion.

RULE.—Divide the diameter, circumference, or number of teeth in the driver, as the case may be, by the diameter, &c., of the pinion.

When there are a Series or Train of Wheels and Pinions.

RULE.—Divide the continued product of the diameter, circumference, or number of teeth in the wheels, by the continued product of the diameter, &c., of the pinions.

EXAMPLE 1.—If a wheel of 32 teeth drive a pinion of 10, upon the axis of which there is one of 30 teeth driving a pinion of 8, what are the revolutions of the last?

$$\frac{32}{10} \times \frac{30}{8} = \frac{960}{80} = 12 \text{ revolutions.}$$

EXAMPLE 2.—The diameters of a train of wheels are 6, 9, 9, 10, and 12 inches; of the pinions, 6, 6, 6, 6, and 6 inches; and the number of revolutions of the driving-shaft or prime mover is 10; what are the revolutions of the last pinion?

$$\frac{6 \times 9 \times 9 \times 10 \times 12 \times 10}{6 \times 6 \times 6 \times 6 \times 6} = \frac{583200}{7776} = 75 \text{ revolutions.}$$

To compute the Proportion that the Velocities of the Wheels in a Train should bear to one another.

RULE.—Subtract the less velocity from the greater, and divide the remainder by one less than the number of wheels in the train; the quotient is the number, arising in arithmetical progression from the less to the greater velocity.

EXAMPLE.—What should be the velocities of 3 wheels to produce 18 revolutions, the driver making 3 ?

$$18 - 3 = \frac{15}{2} = 7{\cdot}5 = \text{number to be added to the velocity of the driver}$$

$$= 7{\cdot}5 + 3 = 10{\cdot}5, \text{ and } 10{\cdot}5 + 7{\cdot}5 = 18 \text{ revolutions.}$$

Hence 3, 10·5, and 18 are the velocities of the three wheels.

To compute the Diameter of a Wheel for a given Pitch and Number of Teeth.

RULE.—Multiply the diameter, in the following table (page 875), for the number of teeth by the pitch, and the product will give the diameter at the pitch circle.

EXAMPLE.—What is the diameter of a wheel to contain 48 teeth of 2·5 inches pitch ?

$$15{\cdot}29 \times 2{\cdot}5 = 38{\cdot}225 \text{ inches.}$$

To compute the Pitch of a Wheel for a given Diameter and Number of Teeth.

RULE.—Divide the diameter of the wheel by the diameter in the table (page 875) for the number of teeth, and the quotient will give the pitch.

EXAMPLE.—What is the pitch of a wheel when the diameter of it is 50·94 inches, and the number of its teeth 80 ?

$$\frac{50{\cdot}94}{25{\cdot}47} = 2 \text{ inches.}$$

To compute the Number of Teeth of a Wheel for a given Diameter and Pitch.

RULE.—Divide the diameter by the pitch, and opposite to the quotient in the table (page 875) is given the number of teeth.

FORMULÆ FOR DETERMINING THE DIMENSIONS OF GEARS BY THE METRIC PITCH.

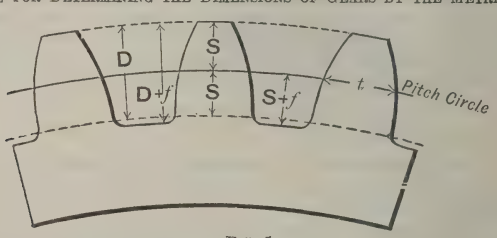

FIG. 1.

M = module; D′ = pitch diameter of gear; D = whole diameter of gear; N = number of teeth in gear; D″ = working depth of teeth; t = thickness of teeth on pitch line; f = amount added to depth for clearance.

Then

$$M = \frac{D'}{N} \text{ or } \frac{D}{N+2}. \qquad D' = N\,M. \qquad D = (N+2)\,M.$$

$$N = \frac{D'}{M} \text{ or } \frac{D}{M} - 2. \qquad D'' = 2\,M. \qquad t = M\,1{\cdot}5708. \qquad f = \frac{M\,1{\cdot}5708}{10}.$$

The module is equal to the part marked 'S' in fig. 1, measured in mm. and parts of mm.

NOTE.—The pitch in this Table is the chordal pitch (p. 872).

CONSTRUCTION OF TEETH OF WHEELS.

P = pitch—the distances between the centres of two teeth in the pitch circle.

Wheel.

D = diameter. C = circumference. M = number of teeth. N = number of revolutions.

Pinion.

d = diameter. c = circumference. m = number of teeth. n = number of revolutions.

EXAMPLE (fig. 2).—Draw the radius, Rr, and pitch circle, PP. Through r draw the line oo' at an angle of 75° to the radius Rr.

Half the angle between two teeth in the

$$\text{wheel, } v = \frac{180}{M} \quad . \quad . \quad . \quad 1.$$

$$\text{pinion, } V = \frac{180}{m} \quad . \quad . \quad . \quad 2.$$

Diameter of the

$$\text{wheel, } D = \frac{d \sin V}{\sin v} \quad . \quad . \quad 3.$$

$$\text{pinion, } d = \frac{D \sin v}{\sin V} \quad . \quad 4.$$

$$D : d = \sin V : \sin v.$$

Pitch (chord) of teeth in the pitch circle

$$\text{wheel, } P = D \sin v \quad . \quad 5.$$

$$\text{pinion, } P = d \sin V \quad . \quad 6.$$

Number of teeth about

$$\text{wheel, } M = \frac{3{\cdot}14D}{P} \quad . \quad 8.$$

$$\text{pinion, } m = \frac{dM}{D} \quad . \quad . \quad 9.$$

Approximate pitch in the wheel, $P = 0{\cdot}028D$ 7.

Depth of tooth, $a = 0{\cdot}46P$* . . . . . 10.

Bottom clearance, $b = 0{\cdot}4P$ . . . . . 11.

Length to pitch line, $c = 0{\cdot}3P$ . . . . . 12.

Distance ro, $d = \frac{P(m+6)}{2(m-11)}$ . . . . . 13.

Distance ro', $e = 0{\cdot}11P\sqrt[3]{m}$ . . . . . 14.

Teeth of very much less length are now used. A length of only half the pitch is ample, the liability to break being greatly reduced.

Mr. M. Longridge considers it sufficient if one pair of teeth engage just before the previous pair go out of contact.

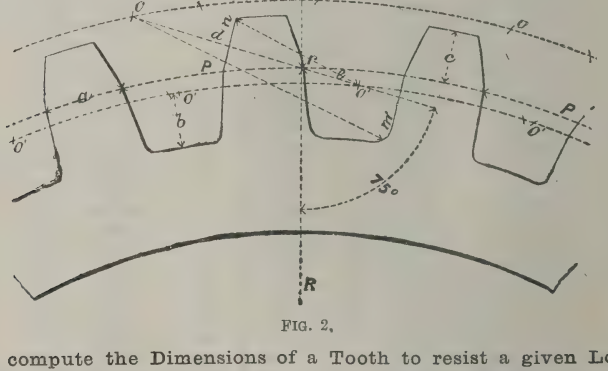

FIG. 2.

To compute the Dimensions of a Tooth to resist a given Load.

RULE.—Multiply extreme load, S, in lbs., at pitch line of wheel, by length, l, of tooth in decimals of a foot; divide product by coefficient, κ, of material of teeth, and quotient will give product of breadth, f, and square of depth, a; f and a both being in inches.

Or,

$$\frac{Sl}{\kappa} = fa^2;$$

from which

$$f = \frac{Sl}{\kappa} \div a^2, \qquad a = \sqrt{\frac{Sl}{\kappa} \div f}, \qquad l = fa^2 \times \frac{\kappa}{S}.$$

The value of κ for cast iron used for this purpose may be taken at 60, and for hardwood at 80.

EXAMPLE.—The load, S, at the pitch line of a cast-iron wheel is 4,886 lbs.; what should be the breadth, f, of the teeth, the length being 2 inches, and the pitch, P, 3 inches?

$l = 2 \div 12 = {\cdot}167$ feet. $\qquad a = {\cdot}46 \times 3 = 1{\cdot}38$ inches.

---

* If a wheel of more than 80 teeth is to gear a pinion of less than 20 teeth, and the wheel and pinion are of the same kind of materials, take the thickness of the tooth in the

$$\text{wheel, } a = P\left(0{\cdot}42 + \frac{m}{700}\right) \quad . \quad . \quad 15.$$

$$\text{pinion, } a = 0{\cdot}5P\left(1 - \frac{m}{350}\right) \quad . \quad 16.$$

A rack is to be considered as a wheel of 200 teeth.

Therefore

$$f = \frac{4886 \times \cdot 167}{60} \div (1 \cdot 38)^2 = 7 \cdot 16 \text{ inches.}$$

A tooth running at a low velocity may be materially reduced in its dimensions compared with one running at a high velocity and with like stress.

Experience has proved that a cast-iron tooth with a pitch of 3 inches and a breadth of 7·5 inches will transmit, at a velocity of 6·66 feet per second, 60 horse-power.

To compute the Depth of a Cast-iron Tooth.

1. *When the load is given.*

RULE.—Extract the square root of the load and multiply it by ·02.

EXAMPLE.—The load to be borne by a tooth is 4,886 lbs.; what should be its depth?

$$\sqrt{4886} \times \cdot 02 = 1 \cdot 4 \text{ inches.}$$

2. *When the Horse-power is given.*

RULE.—Extract the square root of the quotient of the horse-power divided by the velocity in feet per second, and multiply it by ·466.

EXAMPLE.—The horse-power to be transmitted by a tooth is 60, and the velocity of it at its pitch line is 6·66 feet per second; what should be the depth of the tooth?

$$\sqrt{\frac{60}{6 \cdot 66}} \times \cdot 466 = 1 \cdot 398 \text{ inches.}$$

To compute the Horse-power Transmitted by a Wheel.

RULE.—Multiply the pressure at the pitch line by its velocity in feet per minute, and divide the product by 33,000.

EXAMPLE.—What is the horse-power transmitted by a wheel of the dimensions and velocity given in the preceding examples?

$$\frac{4886 \times 6 \cdot 66 \times 60'}{33000} = 59 \cdot 16.$$

For the working load on machine-cut spur wheels Mr. W. Lewis gives the following law:—

$$S = y p b f,$$

where S is the total load in lbs., p the pitch in inches, f the permissible load, and y a factor which varies with the shape of the tooth.

The values of f and y are given in the tables below:—

LEWIS'S VALUES OF f.

Speed in Feet per Minute.	100 or less.	200	300	600	900	1,200	1,800	2,400
Cast iron . .	8,000	6,000	4,800	4,000	3,000	2,400	2,000	1,700
Steel . . .	20,000	15,000	12,000	10,000	7,500	6,000	5,000	4,300

A series of experiments recently made by Prof. G. H. Marx at the Stanford University, Cal., with ten diametral pitch cast-iron 14½ deg. involute gears, shows that the pitch of the gears given by Lewis's formula is somewhat on the heavy side. The Lewis expression is based upon the theory of flexure under the assumption that the entire load is borne by a single tooth, the point of application of the load being the extreme end of the tooth and the direction of the acting force being normal to the tooth profile at that point. The effects of the compressive and shear components are ignored.

Rupture is assumed to take place on a plane section, the position of which is determined by inscribing a parabola of uniform strength with the vertex lying at the intersection of the centre line of the tooth and line of action of the force. The dangerous section is the plane section containing the points of tangency of the parabola with the tooth outline. These assumptions and change in stress with change in speed are too severe for accurate machine-cut gears.

In view of the fact, however, that gears, although originally accurately cut and mounted, when run under severe conditions wear away from their true form and tend to take the load on one pair of teeth, it would be unwise to discard the values given by Lewis until some data, more complete than that presented by Prof. Marx, are available. It is known that small test specimens sustain higher stresses than large pieces, and for this reason the values obtained for ten diametral pitch gears may be misleading when applied to larger pitches.

Mill Gearing.

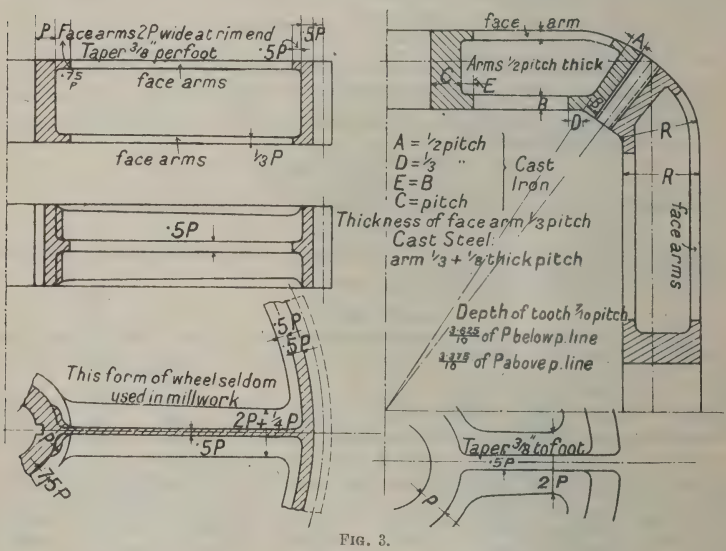

FIG. 3.

Fig. 3 shows the proportions of tooth, arm, faces, bosses, etc., commonly used in mill gearing.

(*J. Nuttall.*)

To Design Wheel Teeth.

EPICYCLOIDAL TEETH.

The correct curves of wheel teeth on the epicycloidal principle are drawn by rolling curves. The same rolling circle is needed for both points and flanks of every wheel in a set. Let A, fig. 4, represent the pitch circle of a wheel, and B the rolling circle. A notch is cut in the edge of B, and a steel point placed firmly in a small clamp, fig. 5, so that its point is on the circle. If this circle be now pressed against A and steadily revolved it will describe a curve on a piece of finely sandpapered tin plate, *t*, laid beneath, as shown at *c*. This is the curve of the tooth point.

Similarly if D, fig. 6, is the template of the inside of the pitch circle of the wheel, the same process will give the curve *e* for the flanks of the teeth. It is considered best practice to make two wheels to suit each other rather than a set; when this is done the points of wheel teeth and the

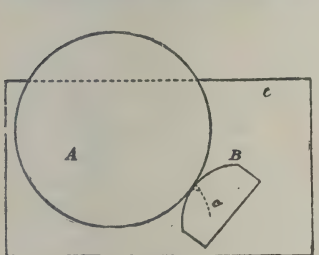

FIG. 4.

FIG. 5.

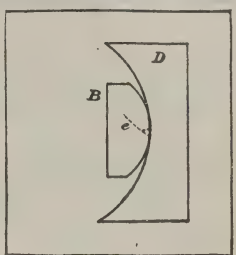

FIG. 6.

flanks of the pinion are described with one rolling curve whose diameter is the radius of the pinion, while the points of the pinion teeth and the flanks of the wheel teeth are described with a rolling circle whose diameter is the radius of the wheel.

CYCLOIDAL TEETH.

In this class of gear the mating parts of a pair of wheels are convex and concave, and a comparatively large surface is in contact with a resulting small amount of wear. As the teeth profiles are developed by two circles which roll inside and outside the pitch circle, and the path of contact is made up of two curves which change their direction at the pitch point, i.e., the point of intersection of a line drawn through the wheel centres and the pitch circles, it is essential for quiet running and no back lash that the shaft centres are exactly correct. Should the centres be initially incorrect or become so due to wear at the bearing or journal, all rolling motion is lost and excessive noise and wear will result. Cycloidal gears are very difficult to accurately generate in the machine, and in the case of a set of wheels from 12 teeth to rack, with profiles generated by rolling circles greater in diameter than half the diameter of the smallest pinion, the flanks are under-cut and cannot be hobbed or cut with a rotary cutter. A rolling circle $\frac{3}{8}$ in. diameter is the smallest pinion in the set that has been generally preferred.

By making the diameter of the rolling circle equal to the radius of the smallest pinion the teeth have radial flanks and are thinner at the root than at the pitch line, but when the rolling circle is less than the radius of the smallest pinion the teeth are thicker at the root than at the pitch line and such teeth can be cut with a rotary cutter. As the diameter of the rolling circle decreases the angle of obliquity of action or angle of pressure increases. Cycloids are difficult to draw correctly, and the true curves are usually approximated by circular arcs by the pattern-maker when striking out the pattern, thus introducing a possible error. Whilst this class of gear has good wearing qualities, high speeds have made its defects, which are scarcely noticeable at low speeds, very pronounced, and has been largely displaced by involute gearing.

INVOLUTE TEETH.

Involute teeth have the advantage of being a continuous curve from root to point, and all involute teeth of the same pitch will correctly gear together.

Let AB and CD, fig. 7, be the pitch circles of any two wheels, and EF their line of centres. Through the intersection of the pitch circles and EF draw MN, making an angle with EF of about 75°. In the figure it is drawn at 60° for plainness. Circles *nn* and *ss* are drawn touching MN. These two circles are the base circles from which the teeth curves are described. The method is then the same as with the epicycloidal tooth, but the rolling circle is simply a straight edge, as shown at K, fig. 8.

The path of contact in involute teeth gears is a straight line, tangential to the base circle, and permits of the teeth meshing correctly together when the shaft centres are slightly inexact. Should the wheel centres be slightly in excess of their correct dimension the angle of the path of contact is increased, but it still cuts the pitch lines at the pitch point; the same tooth profiles are obtained, and the disadvantages are a slightly increased back lash and pressure on the journals. The mating parts are both convex, the surface in contact is small, and the wear large in comparison with cycloidal gears. An angle of obliquity of action, equal to $14\frac{1}{2}°$, has hitherto been in general use, but the tendency to-day is to use a 20° to $22\frac{1}{2}°$ obliquity and a smaller tooth addendum. With the $14\frac{1}{2}°$ pressure angle and height of tooth above the pitch line of 0·318 pitch there is excessive relative sliding at the points of the teeth, thereby causing extensive local wear, and with a 12-tooth pinion engaging with a straight toothed rack, having an included angle of 29°

between the working faces, there is severe interference between the flanks of the pinion teeth and the points of the rack teeth, which, if cut away, reduces the path of contact to less than a pitch length. To avoid such, the shape of both mating teeth have to be modified if the angle and minimum number of teeth (12) are adhered to. Up to the present the practice has been to

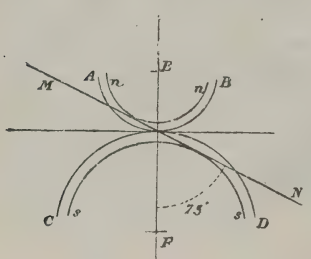

FIG. 7.

FIG. 8.

modify the shape of the tooth by making the flanks of the pinion teeth radial and rounding off the faces of the rack teeth. The introduction of this uncertain quantity has led many practitioners to adopt the 20° or 22½° angle of obliquity where the true form can be obtained without interference at the working surfaces.

With an angle of obliquity of 20° to 22½° the pressure at the bearings is increased 5 to 6 per cent. With a pinion of 28 teeth and angle of pressure of 14½° interference is avoided, as is also the case with a 20-tooth pinion having pressure angle of 20°. Interference may be avoided in a 12-tooth pinion by decreasing the addendum to $\frac{1}{8}$ module when the angle of obliquity is 20° or $\frac{7}{8}$ module when the angle of obliquity is 22½°. In both cases a minimum arc of contact equal to $1\frac{1}{8}$ pitch can be obtained. Such teeth are termed 'stub' teeth, and in comparison with the standard tooth are thicker at the roots and therefore stronger. Further, by removing the points of the teeth where the sliding action is greatest, a better rolling action results, and the efficiency of the gear is increased.

SPUR GEARING.

It has been observed by Mr. S. H. Rowley that defects are at times noticed in cut gears, generally manifested in noisy running. If the noise be what is termed a revolution noise, it is generally due to a thick tooth or teeth, caused by inaccurate spacing. Some wheels will be found to run quietly in one direction and noisily in the opposite. Investigation will show that the teeth have not been cut radially. Both these defects are due to careless work from the ordinary type of gear cutters using disc cutters, and are the outcome of inaccurate setting. If neither of these faults can be found, then look to the form of tooth, and it can be stated almost with certainty that it is a hobbed gear, and the hob used is of faulty shape.

These are all faults apart from erecting, as it is well known that gears running out of alignment, and also at too close centres, will produce a noise, besides numerous other causes which might be enumerated.

Speaking in broad terms of teeth in general, for strength, a flank as broad as possible is desirable; for efficiency, a short line of action; and for quietness and smoothness of running, a longer one.

For accurately checking a tooth, more especially of a pinion, it is necessary when setting the tooth micrometer to make an allowance on account of the chordal arc differing from the tangent, thus altering the width; also the location of the pitch line on the sides of the teeth falling below the position in the middle of the tooth calls for a correction in the addendum.

For spur gearing running at high speeds, say of over 1,200 ft. per min. on the pitch line (general engineering work and not motor gears is here referred to), the following practices are adopted to eliminate noise. Employ fine pitches with wide faces, in preference to coarse pitches and narrow faces. Practice has altered very considerably in this direction in recent years. The teeth, instead of being cut parallel to the face, are sometimes cut on an angle, or more strictly spiral, the wheel being of one hand and the pinion of the opposite. The objection is the side thrust which is set up. To overcome this, a double helical is often used, which is a costly form of gearing, and when made solid often unsatisfactory. Experiences with different angles for the single helical go to show that with a gear of normal face an angle of about 15° gives good results—silent running combined with only slight end thrust. If it be possible to increase the face, the angle may be reduced. Phosphor bronze and steel have proved more

silent than both wheels of the same metal. Fibre wheels have also been used with good results, and when flanged with metal plates for quite considerable powers; their life is not, however, a very long one. If the load be a heavy one, the most general practice is to use a raw-hide pinion. If this be properly made and treated, it will often outlast a cast-iron wheel, and is as durable and strong as, if not stronger than, cast iron to resist shocks.

Mr. Daniel Adamson * states that in 1899 he adopted for the teeth of spur wheels on cranes an addendum of 0·25 pitch with a dedendum of 0·32 and angle of obliquity of 14½°. These proportions do not, however, prevent 'interference' if a straight-sided rack tooth is used, as is desirable for reason of accurate reproduction. To avoid this objection the angle of obliquity must be increased to 22½° if a 12-tooth pinion is to be the least of the series; but if 14 teeth can be adopted, then 20° is sufficient.

In addition to facilitating accurate construction, by permitting generation, these modifications have a further advantage in giving a stronger form of tooth, thus allowing a finer pitch to be used for given diameters of wheel and pinion. Reducing the pitch in this manner increases the number of teeth in contact, improves the durability, and reduces the noise. The rate of wear is also reduced when more teeth are in gear simultaneously, because the contact between the teeth takes place nearer the pitch line, where there is less relative sliding, and for the same reason the loss of power by friction between the teeth is reduced.

The theoretical number of teeth (stub) in contact depending upon the number of teeth in the wheel and pinion are given in the table below.

DURATION OF CONTACT.

For Involute Teeth 20° Obliquity. Addendum, one-quarter of Circular Pitch.

No. of Teeth.	12	15	20	30	36	45	60	75	100	150

75	1·30	1·33	1·36	1·39	1·41	1·42	1·44	1·45	1·46	1·47
100	1·32	1·34	1·37	1·40	1·42	1·43	1·45	1·46	1·47	1·48
150	1·33	1·35	1·38	1·41	1·43	1·44	1·46	1·47	1·48	1·49

The factors to be considered when estimating suitable proportions to resist wear are:

P = load to be transmitted at the pitch-line; N = number of revolutions per min.; e = estimated number of teeth in contact; b = breadth of the teeth.

The average of 50 examples by Mr. R. Livingstone, of raw-hide pinions 'in service and giving satisfaction' gives $\frac{PN}{b} = 112{,}000$, and $\frac{P}{b} = 115$ lbs. per inch of face. Lasche gives three examples of Delta-metal pinions working satisfactorily with steel wheels on crane motors in which the average for $\frac{PN}{eb} = 100{,}000$. For steel pinions gearing with steel wheels in intermittent crane work, Mr. Adamson has found that a maximum of 130,000 for $\frac{PN}{eb}$ and 53,300 for raw-hide pinions under similar conditions, works quite satisfactorily.

With regard to speed, Mr. W. H. Thornberry gives 1,800 ft. per min. as the greatest at which ordinary cast iron wheels may be safely run, and 3,000 ft. per min. for machine-cut wheels. The same authority quotes examples up to 4,000 and 5,000 ft. per min., but recommends caution

* See Proc. Inst. of Mech. Engrs., 1916.

before adopting such speeds. A pair of mortise teeth bevel wheels at Niagara transmits 1,100 h.p. at 3,930 ft. per min. These have 43 and 33 teeth, $5\frac{1}{2}$ pitch and 20 ins. face. After $6\frac{1}{2}$ years these wheels were running satisfactorily, except that the wooden teeth only lasted 6 to 8 weeks. At the same place a pair of cast steel bevel wheels transmitted 1,300 h.p. at 3,900 ft. per min. The teeth were 20 ins. wide, 5 ins. pitch, and whilst satisfactory as far as abrasion is concerned they occasionally gave trouble by breaking out.

Christie states that a pair of spur wheels transmitted 3,300 h.p. at 2,500 ft. per min., and the load on the teeth was nearly 2,100 lbs. per in. of face. The pinion was made of fluid pressed steel containing 0·86 per cent. C, 0·51 per cent. Mn, 0·27 per cent. Si. The wheel was an annealed steel casting containing 0·47 per cent. C, and 0·66 per cent. Mn.

The pinion should always be of harder material than the wheel, in order to equalise the wear. Mild steel gearing up to, say, 0·3 per cent. carbon gives trouble by abrasion, and also by change of form due to the percussive action experienced under heavy loads. High carbon steel, say 0·6 per cent. carbon or above, or nickel steel, should be used, and preferably the latter, as it meets all requirements without a complicated heat treatment.

In gearing, large revolving masses—as, for example, armatures of motors—should be separated from adjoining masses such as large gear wheels of the second motion, by some elastic medium such as a length of shafting or a flexible coupling (Section XXI). This is intended to allow for slight variations in the angular velocity, due to unavoidable errors in cutting the teeth, to take place without giving rise to destructive loads between the teeth. The stresses due to inaccuracies in the spacing of the teeth may exceed the working stress. With an error of only 0·2 per cent. in the pitch the excess load due to acceleration and retardation may amount to as much as 28 times the load transmitted. Such loads increase as the square of the mean pitch-line velocity and as the mass of the wheel considered.

MAAG GEARING.

(*Sulzer Bros.*, 31 *Bedford Square, London, W.C.* 1.)

Maag gearing introduces certain novel features both in the production of gears and the shape of tooth, which are claimed to overcome the defects inherent in the ordinary standard form of gearing.

The method of cutting Maag gears is on the generating principle, producing theoretically correct involute tooth profiles *free from any standardisation.*

The arrangement is not confined to a special pressure angle, nor to any standard proportions of tooth, there is, therefore, a free choice in the pitch allowed; it is immaterial whether the pitch be 3 diametral, 3·23 diametral, 12·57 mm., or $1\frac{13}{16}$ in., etc.

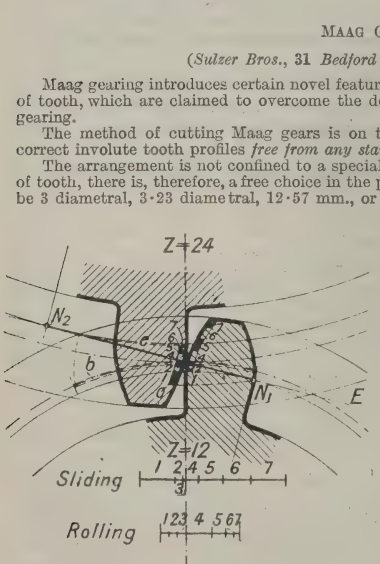

FIG. 9.

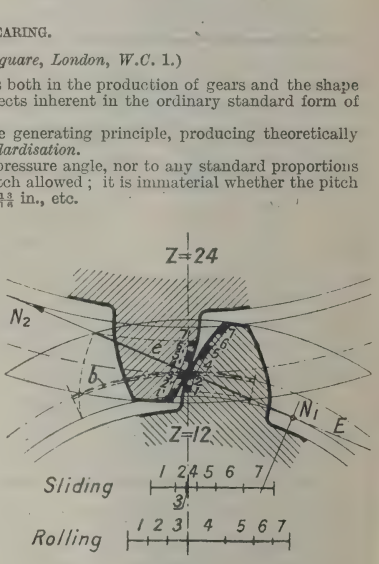

FIG. 10.

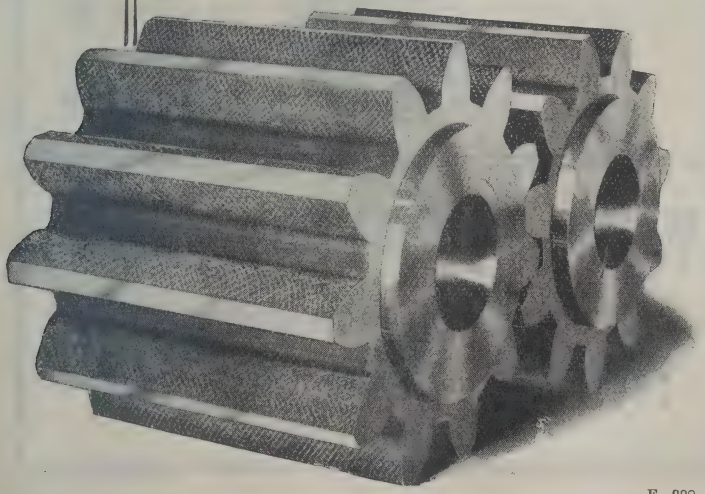
Any pitch whatever can be cut, using the same standard tool. This tool is in the form of a straight-sided rack-cutter, which generates involutes on a well-known principle for the production of this type of tooth. In addition to the special form of tooth, which is designed to give the best theoretical shape for each individual set of gears, the Maag gears are noticeable for the fact that the tooth surfaces are case-hardened and ground with mathematical precision on the generating principle; this is accomplished by means of simple saucer-shaped grinding wheels, in which the projection of the edge of the wheel forms the plane of an imaginary straight-sided rack. Two such wheels set at the correct angle thus form the sides of the rack, and involutes



Precision !

THE MAAG SYSTEM of Gear Cutting and Grinding enables you to produce the best theoretical form of tooth, ensuring maximum rolling and minimum sliding contact without the use of special tools or cutters.

are generated by grinding in the same manner as in the gear-cutting machine. As the edge of these saucer-shaped discs must always lie in a true plane, it is obvious that the surfaces generated must be perfect involutes, and the wear of the grinding discs only affects the thickness of the individual tooth ; this is, however, compensated for by an automatic device which automatically keeps the planes of the grinding wheels in their exact position.

In the Maag system, the shape of the tooth and the accuracy with which it is formed enable, it is claimed, much higher loads and much higher speeds to be obtained than with any other form of gearing. Thus, for example, there are applications of Maag gearing which operate at peripheral speeds of 10,000 ft. per min. and even up to 15,000 ft. per min., while the load per inch width of tooth can be taken as at least double that possible with the double helical form of gearing. An important example is in the new Swiss locomotives of 2,500 B.H.P., where the Maag gearing has replaced the ordinary double helical type.

Fig. 9 represents two teeth of a standard drive 12/24 as made by the common series-cutter method and is in frequent use in machine tools, cranes, etc. Fig. 10 shows teeth of the same drive made by the Maag method.

The most conspicuous difference is in the roots of the teeth. The teeth of both drives are thickest near the base circles, but while these circles are located in Fig. 9 very near the pitch circles and therefore far away from the root-circles, they appear in Fig. 10 shifted much farther towards the root-circles. It is easily seen, then, that the radial extensions of the profile in Fig. 9, due to their length, converge greatly towards the root-circles, weakening the teeth, especially the one of the 12-tooth pinion. This is not noticeable in Fig. 10, the radial profile extensions being short.

Since with the use of series-cutters all teeth are equally thick at the pitch line, that is, equal to half the pitch, the teeth must be weaker at the root the smaller the number of teeth in the gear. Fig. 10 shows that this is not the case with Maag gears ; for by proper distribution of addendum and dedendum, as well as thickness at the pitch lines, a nearly equal thickness of tooth at the root in both wheels is secured.

Taking the thickness of tooth of the 12-tooth pinion as equal to 1, this thickness for the same pitch in the Maag gear is 1·31, which means that the tooth could be loaded $1{\cdot}32^2 = 1{\cdot}7$ times as heavily, or for the same load a pitch 1·31 times smaller, or a tooth number 1·31 times larger could be used ; in other words, in place of a drive 12/24 made by the series-cutter method a Maag drive 16/32 could be built into the same centre distance, and this fact, even if it were alone, would greatly improve the conditions of mesh and wear.

Heat-Treated Gears.

The conditions under which gear wheels are employed can generally be considered as coming under two heads : (1) For the purpose of transmitting power under approximately constant conditions of load and speed ; and (2) under conditions which subject the wheels to shock or reversal of stress.

In the first case, resistance to wear is the chief consideration, and for this purpose case-hardened gears are eminently suited, but under the second condition oil-hardened gears of special steel are usually necessary. Cast-steel gears are frequently used where resistance to wear is the principal consideration and where the number of gears required are few. Should the gears be small these are usually cast from a pattern, but if large they are frequently machine-moulded, and in both cases sufficient is left on the teeth to ensure their cleaning up in machining. Where a large number of gears are required, it has become the practice to obtain these from mild steel stampings, the teeth being roughly formed in the process and subsequently by the cutter in the machine. Such gears are extensively used in their soft state, but where the conditions of wear are somewhat severe, these are usually case-hardened. Where the speeds are high and conditions very severe, such teeth are liable to chip, and an alloy steel of nickel or nickel chrome is substituted. The alloys commonly used are nickel (3 to 5 per cent.), and nickel chrome (carbon ·15, chrome ·5 to 1·5, nickel 1·5 to 5). Chrome vanadium compositions are also being used for case-hardening gears. These gears should be carburised at a temperature of 880° C. and allowed to cool in the box, afterwards they should be reheated to about 820° C. and quenched in water. This procedure gives a tougher core than is obtained when the steel is quenched direct from the carburising temperature. It may be necessary to protect some parts against carburising. For this purpose a shield of copper, copper-plating, or asbestos pad secured with the fireclay, are frequently employed.

Oil-Toughened Gears.

In this case the straight nickels and nickel chrome steels are most extensively used. With such gears it is advisable to anneal these after rough machining in order to break down crystallisation set up during forging. The annealing temperature for these steels should be about 800° C., and the quenching temperature about 820° C. For moderate service conditions nickel chrome steel which has been cooled off in an air blast has been found to give excellent results.

Heat-Treatment for Gears.

In order to treat chrome-nickel steel gears of 8 diametral pitch so that they will have a soft core suitable to withstand shock, first heat the gears in carburising pots to 1,600° F., for seven hours. Then remove the pots from the furnace and allow the box and work to cool over

night. The next morning empty the pots and reheat the gears to 1,400° F. Then take out and quench in oil. This is known as the refining heat. Reheat the gears to 1,450° F., and quench in water, and the gears will be found to be properly hardened. Several gears should be treated in this way, and the teeth should be broken from one in order to ascertain the depth of case on the teeth, which should be $\frac{1}{32}$ in. (*'Machinery.'*)

Non-Resonant Gears.

Raw-Hide Pinions.

When a raw-hide pinion is adopted, the minimum number of teeth should be, if possible, twenty, and in no case should less than fifteen be used. Practice varies as to the shrouding, some users preferring gun-metal with the teeth cut through, and others steel plates solid. To ensure the metal wheel coming in contact with the hide only, the pinion faces should be made slightly wider than the wheel. It is advisable to have the faces at least three times the pitch.

Lubrication.

It is common knowledge that no grease nor oil should be allowed near a raw-hide gear, yet there is no rule more frequently disregarded than this, the result being speedy destruction of the pinion. If the hide, when in use, should become unduly dry, a sparing coat of raw linseed oil will tend to preserve it.

Ordinary hydrocarbon oil is most destructive to raw-hide pinions. One of the best compounds for the purpose is given in *Marine Engineering of Canada*, as follows:—Plumbago, 15 per cent.; rosin oil, 55 per cent.; rosin, 30 per cent.

Cloth and paper pinions can be lubricated, without injury, with ordinary oil.

Resilient Steel Gears
(Seymour's Patent).

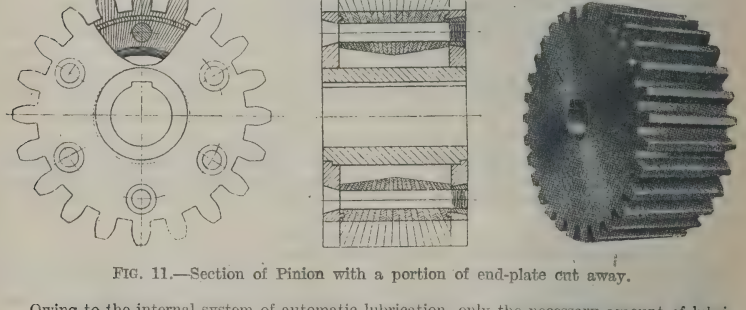
(Thomas Summerson & Sons, Ltd., Darlington.)

These gears are designed and constructed specially for drives where the strength and durability of steel gears is necessary, but where the noise accruing from their use would not be permissible.

The portion of the gear-wheel from which the teeth are formed is made up of steel laminæ, having an ultimate tensile stress of 45 tons, the boss and shroud plates being constructed of cast or forged steel.

The resilience of the working surfaces of the teeth afforded by this method of construction is sufficient to render the running of the gears as noiseless (even when the same are considerably overloaded) as gears constructed of raw hide, paper, and woven fabrics.

On account of the superior strength and durability of steel over the other substances named, the resilient steel gears transmit many times the load for any given size of tooth, and their life is longer proportionally.



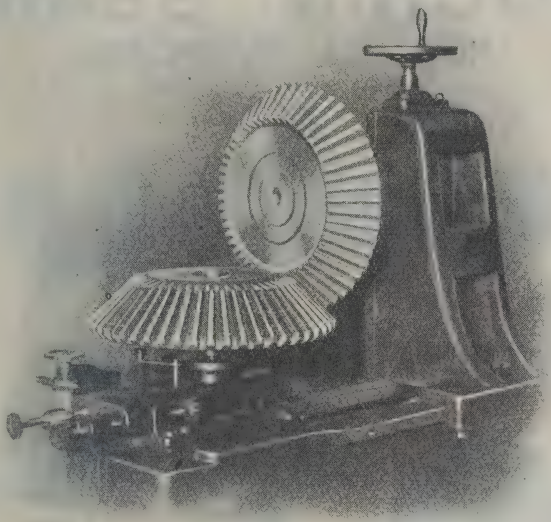


FIG. 11.—Section of Pinion with a portion of end-plate cut away.

Owing to the internal system of automatic lubrication, only the necessary amount of lubricant is supplied to the surfaces of the teeth, thus preventing waste and effecting a saving of $3\frac{1}{2}$ to 4 per cent. of the power transmitted.

Important improvements in the construction of these gears have been made, notably the connecting together of the lateral extremities of the laminæ by welding, thus the laminæ are firmly secured together independently of the support supplied by the shroud plates and bolts.

These gears have been successfully applied to almost every class of drive, including mine

Rawhide Pinion and Cast Iron Mitre Wheel on Test.

and quarry machinery and haulage, electric motor drives, pumps, air compressors, machine tools, cranes, etc. etc.

Resilient steel gears are being constructed for transmitting ever increasing horse-power, some under construction now have been designed to transmit upwards of 750 h.p. at 1,800 ft. per minute.

Fig. 11 shows laminæ and shroud plates held together with bolts.

The cavity between the boss and the laminæ is the receptacle for the lubricant; centrifugal force propels the lubricant radially outwards between the laminæ, thus efficiently lubricating the entire working surface of the teeth.

The power transmitted by such gears can be calculated from the following formula :—

$$F = \frac{HP \times 1000}{K \times N \times R'}$$

where

F = Face of pinion in inches; N = No. of teeth; K = Factor for each pitch (see table); R = Revolutions of pinion per minute; HP = Horse-power to be transmitted.

Helical Teeth-Gearing.

This form of gearing has been somewhat extensively adopted, especially in cotton-spinning machines. It consists, when the direction of the motion is simply to be changed to an angle of 90°, in forming the teeth upon the periphery of the pair at an angle of 45° to the respective axes of the wheels, as in figs. 12 and 13. It will then be perceived that if the sloped teeth be presented to each other in such a way as to have exactly the same horizontal angle, the wheels will gear together, and motion being communicated to one axis, the same will be transmitted to the

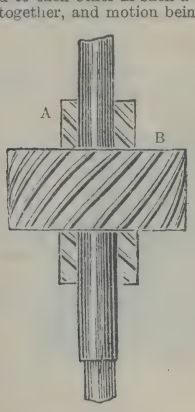

FIG. 12.

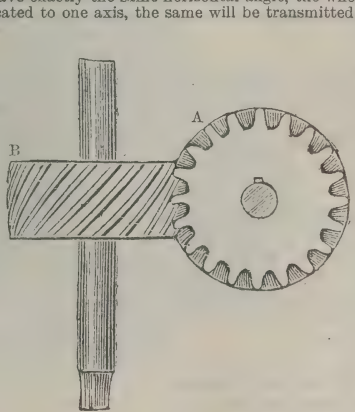

FIG. 13.

other at a right angle to it, as in a common bevel pair. Thus, if the wheel A upon a horizontal shaft has the teeth formed upon its circumference at an angle of 45° to the plane of its axis, it can gear with a similar wheel, B, upon a vertical axis. Let it be upon the driving-shaft, and the motion will be changed in direction, as if A and B were a pair of bevel wheels of the ordinary kind, and, as with bevels generally, the direction of motion will be changed through an equal angle to the sum of the angles which the teeth of the wheels of the pair form with their respective axes. The objection in respect of lateral or end pressure may, in the case of a vertical shaft, be partly got over by sloping the teeth so that the tendency is to lift the shaft, and not force it down into the stop bearing; this would act to keep the wheels in close contact, by reason of the weight of

the vertical shaft, and at the same time reduce the friction between the end of that shaft and its stop bearing. This renders this form of gearing preferable to skew bevels when employed upon vertical shafts.

The gears shown by figs. 12 and 13 may be turned up in the lathe, because the teeth are simply portions of spirals wound about the circumference of the wheel. For a pair of wheels of equal diameter a cylindrical piece equal in length to the required breadth of the two wheels is turned up in the lathe, and the teeth may be cut in the same manner as cutting a thread in the lathe; that is to say, by traversing the tool the requisite distance per lathe revolution. In pitches above about ¼ inch it will be necessary to shape one side of the tooth at a time, on account of the breadth of the cutting edges. After the spiral (for the teeth are really spirals) is finished, the piece may be cut in two in the lathe, and each half will form a wheel.

Double Helical Teeth-Gearing.

When correctly designed and accurately cut, double helical gearing possesses advantages both in principle and utility which cannot be obtained from any other type of gearing. The advantages are as follows :—

1. Continuity of engagement, which reduces vibration and enables a greater load to be transmitted.

2. Pinions with a small number of teeth can be used, and in this way high ratios can be obtained without using a wheel of abnormal diameter.

3. A higher efficiency than in the case of straight-toothed gearing is obtained. This is due to the different action of the teeth during engagement. In straight cut gears the line of contact lies parallel to the axis of rotation, and consequently the phases of engagement are constantly changing, and the action is uneven. With double helical gearing the line of contact is a curve extending diagonally across the tooth, and all phases of engagement occur simultaneously.

4. Silent running at high speeds is obtained, owing to the gradual engagement and absence of vibration. There is no necessity for using soft pinion materials, such as raw hide or fibre.

It is generally found that a forged steel pinion gearing with a cast-iron wheel gives the best results, if the horse-power is not too high. In certain cases, where high horse-powers or sudden overloads are to be transmitted, pinions made from high carbon or nickel steel, gearing with cast steel wheels should be used.

Spiral Angle of Teeth.

The angle now generally adopted for continnous cut helical gears is 45° when cut by means of end milling process, and 30° when cut on the Sykes' Patent shaping process, which gives a continuous tooth with sharp apex. Staggered helical gears are usually 23°.

The minimum width of face is respectively four and six times the pitch.

Strength of Double Helical Gearing.

The following particulars and formulæ (*The Power Plant Co. Ltd.*) are applicable to double helical gears with staggered or continuous teeth cut by a generating process using hobs, or the Sykes' shaping system, with a spiral angle of 30° or 23° and face width of 6 times the pitch, for ratios up to six to one, afterwards increasing with ratio.

Let p = pitch in inches ; P = tooth pressure in lbs. at pitch line ; W = width of face in inches ; V = pitch line velocity in feet per min. ; r = ratio of reduction ; K = permissible stress (taken from curve, fig. 14) :

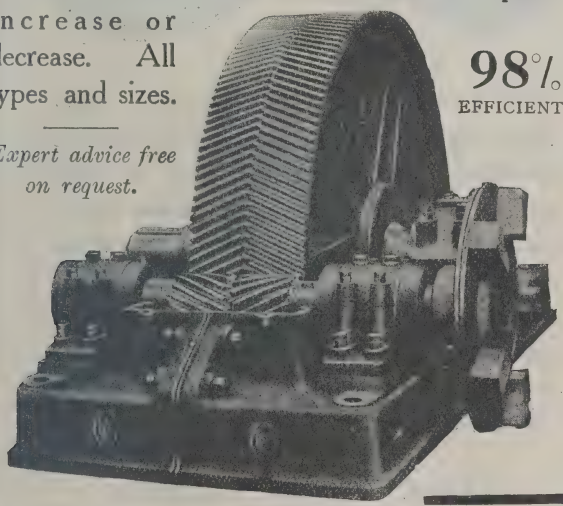
$$P = \frac{\text{B.H.P.} \times 33000}{V} = \frac{p.W.K.}{2}$$

For ratios up to 6 to 1, $$p = \sqrt{\frac{P}{3 \times K}}$$

For ratios between 6 and 10 to 1, $W = rp$, $$p = \sqrt{\frac{2{\cdot}5\ P}{rk}}$$

For ratios above 10 to 1 special treatment is advisable, and no fixed rules can be laid down; each drive should be considered with regard to the general conditions.

Proportions of Teeth.



Thickness of tooth $= \frac{P}{2}$; Addendum $= \frac{{\cdot}89 \times P}{\pi}$; Dedendum $= \frac{1{\cdot}05 \times P}{\pi}$

Double Helical Gears

OUR DOUBLE HELICAL GEARS are cut from Solid Blanks on accurate Gear Generating Machines. Tooth Engagement is smooth and certain and side-play is obviated. We make Gears for single reduction to ratios as high as 20 : 1. The ideal transmission for speed increase or decrease. All types and sizes.

In the case of helical gears with continuous teeth, the formulæ vary according to the kind of machinery for which the gears are intended, and they are very numerous.

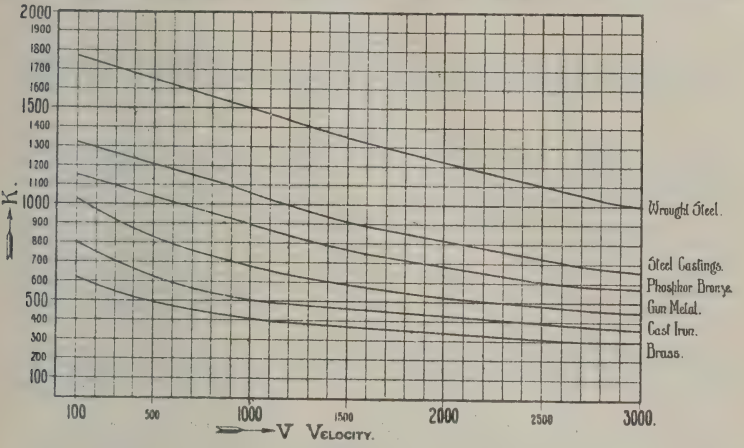

Fig. 14.

Bevel Wheel Teeth.

A and B, fig. 15, are a pair of bevel wheels revolving on shafts OD and OE. Join OC through the pitch contact of the wheels, and join DE at right angles to OC, and cutting the axes of

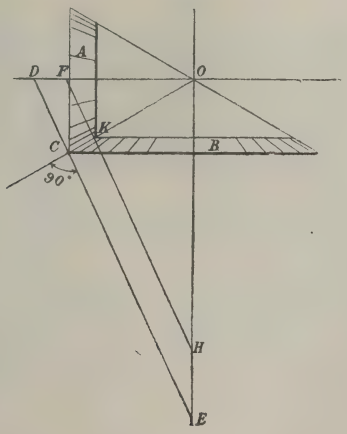

Fig. 15.

revolution at D and E. Then CD and CE will be the virtual or instantaneous radii of the wheels A and B, and these radii are those of two spur wheels which will gear similarly to the wheels

A and B, and must be used as the base lines or radii on which the teeth of the bevel wheels A and B must be designed. Similarly, KF and KH are the radii for designing the inner ends of the teeth. The finished tooth lies evenly between the two end shapes thus found.

Gees Teeth.

Gees teeth are suited to run in one direction only. Their working faces are of any ordinary form, and their idle faces are described with very small rolling circles. This gives a very sloping back to the teeth. They are very strong and run quietly.

Turbine Gears.

This name has come into use for gears running at very high pitch line velocities (3,000 to 12,000 ft. per min.), and applied either to reduce speed of steam turbine to that of mill shaft, standard speed electric generator, propelier, etc., or to increase speed from high speed internal combustion engines, electric motors, etc., to that of rotary pumps, blowers, and compressors.

For such purposes helical gears are almost universally used, as they possess among other advantages an efficiency of 98 per cent. To obtain smooth running the utmost accuracy in the cutting of the teeth is requisite. The teeth may be cut with an end miller, planed or shaped, and hob milled. The two latter processes have the advantage that the teeth are automatically generated from a straight-sided cutter. A creeping motion is provided in some of the most recent designs of gear hobbing machines, so that any inaccuracy in the master worm wheel is distributed in spirals on the gear wheel, instead of being parallel to the axis.

Helical gears for geared turbines are invariably made with involute teeth, and the angle of obliquity of the tooth adopted is usually $14\frac{1}{2}°$. The bottom of the tooth must be well rounded and have no sharp corners. The angle of the tooth relative to the axis now commonly used is about 30°.

The Power Plant Co Ltd. of West Drayton use for the pinions, alloyed steels (nickel or chrome nickel steel) and for the wheels above velocities of 4,000 ft. per min., forged steel rims.

The calculation must start from the requisite pinion diameter to transmit a given load without exceeding the very narrow limits within which bending and twisting are allowed.

With gears where the pinion active face exceeds three times the pitch diameter, three bearings are invariably required for the pinion, to resist bending. The slightest inaccuracies in pitching and setting of the wheels, and comparatively small bending and twisting strains are liable to affect turbine gears very adversely, but these effects can be counteracted by special designs such as the wheels with the pressure compensating device as manufactured by the above company.

Pitch.

Fine pitches give silent running at high speeds, and a normal pitch, that is, the pitch measured at right angles to the teeth, of 0·583 in. (or $\frac{7}{12}$ in.) has been largely used in this country. For small pinions, or where extreme silence is of importance, 0·4 in. in pitch has been used.

The number of teeth should not be less than 19, with normal addendum and dedendum.

An ample supply of oil is imperative, not only to lubricate the teeth, but also to carry off the heat generated. For this purpose it is usual to have $\frac{1}{4}$ in. to $\frac{3}{16}$ in. nozzles of about 5 ins. pitch squirting oil under a pressure of 10 to 20 lbs. per square inch on to the line of contact between the gear wheels. The quantity of oil is about 1 gallon per minute per 100 to 150 h.p. transmitted. The case must be well drained, otherwise if the wheel dips into the oil at the bottom much heat will be generated by the churning of the oil.

The power transmitted by a pinion depends upon the allowable tooth speed, load per inch run, and the distortion due to the deflection and twist of the pinion, which must be so small that the distribution of the load on the teeth is uniform. Tooth speed up to 120 ft. per second is common.

The load on the teeth is generally reckoned in pounds per inch run, and is of course the same whether per axial inch or per inch of tooth along the helix. It is determined by the safe bending stress, pressure at point of contact, and by the danger of the oil film failing. The bending stresses are usually low and ignored. For similar crushing stress on the material of the tool, the load (p) per inch run in pounds $= ad$; where d is the pitch diameter of the pinion in inches and a is a constant. The stress on the oil film will obey some such law as $p = bd^n$. Mr. H. M. Martin (see *Engineering*, August 11, 1916) gives $n = \frac{1}{2}$. The conditions mean that up to a certain diameter $p = ad$, and that above it $p = bd^{\frac{1}{2}}$.

Messrs. Parsons take $a = 80$ and $b = 175$, but values of $b = 250$ have been used.

The distortion of the pinion is made up of two items—the twist due to the torque transmitted and the bending due to the load on the teeth. The load on the tooth is assumed to be uniform, and the effective diameter of the pinion is the pitch diameter.

FIG. 16.

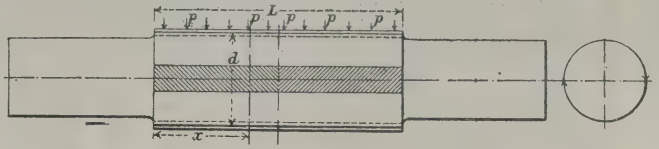

FIG. 17.

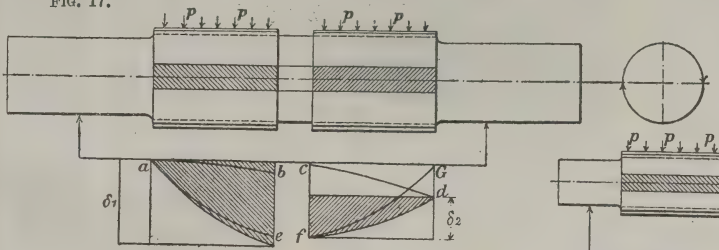

FIG. 18.

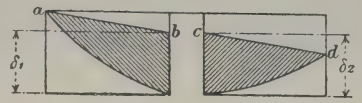

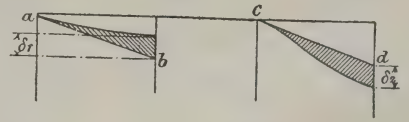

FIG. 20.

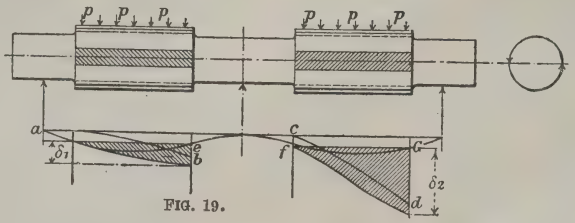

FIG. 19.

At any point x in fig. 16, the torque T is:

$$\frac{pxd}{2} = \frac{2fI}{d} = \frac{\pi f d^3}{16}$$

where f is the shear stress at the circumference of the pinion, and I is the polar moment of inertia or $\frac{\pi d^4}{32}$. Hence it follows that $f = \frac{8px}{\pi d^2}$. If N is the modulus of rigidity, which for steel is 12,000,000 lbs. per square inch:

$$\frac{dy}{dx} = \frac{f}{N} = \frac{8px}{\pi N d^2}$$

$$y = \frac{4p}{\pi N} \frac{x^2}{d}$$

which is a parabola. The twist in the first half of the pinion is:

$$y_1 = \frac{p}{\pi N} \frac{l^2}{d}$$

and in the second half:

$$y_2 = \frac{3p}{\pi N} \frac{l^2}{d}$$

There are two cases to consider: the case where there is no centre bearing and the pinion is supported from the ends, as in fig. 17, and the case where there is a centre bearing, as in fig. 19.

The deflection of the pinion can be calculated in the usual way, and is shown by the curves *ae* and *fg*. To this must be added the twist, as shown by the curves *ab* and *cd*. Adding these together, the total distortion is shown by the shaded area, the maximum distortions in each half of the pinion being δ_1 and δ_2. The gap shown in the middle of the pinion is to enable the hob to clear the teeth in each half.

If, in the case of a pinion with a centre bearing, the pinion took up the position *abcd* shown in fig. 20, the effect of the distortion of the pinion is reduced.

In the case of a pinion without a centre bearing, the effect is only small, as shown in fig. 18.

In the case of a pinion without a centre bearing the bending is the chief consideration, whereas in the case of a pinion with a centre bearing the twist is the chief thing.

The allowable distortion should not exceed $\frac{1}{1000}$ in.

(*Prof. Gerald Stoney, F.R.S., D.Sc.*, '*Trans. Manchester Assoc. of Engineers*, 1919.')

A load of 300 lbs. per inch of tooth (measured axially) is a good average figure. Usually the pinion is made of nickel steel or chrome steel. The torsional stress in high-speed shafts varies from 1,500 to 2,500 lbs., and in the low-speed shafts from 3,000 to 3,500 lbs.

Pitches as high as 0·9 in. have been used for high-speed pinions, and 2 ins. for second reduction pinions.

Single reduction gears having a velocity ratio of 28 to 1 have been used, but this value is extreme.

Worm Gearing.

To be correct, a worm gear should have the cross-section of the wheel hollowed on the teeth to the radius of the worm. The correct form of tooth is peculiar and difficult to understand and make, but it can be accurately formed by a simple device. Let *abc*, fig. 20A, p 891, represent the pitch line of a wheel and *b* the form of a tooth suitable to drive a rack.

A circle *de* is fitted with a thin steel tooth of this shape, and this circle is revolved with a wax worm W at the correct speed at which the worm and wheel will turn. The tooth *b* will cut a thread on the worm of the correct shape at all points, from end to end of the worm. If now this worm be cast and fluted to form a cutter it will serve to cut a worm wheel, or it may be used to mould a worm wheel in wax by the process of revolution.

For good working, worms should be short, and worm wheels of large diameter, and the worm should run in an oil bath. The best materials to work together are phosphor bronze and steel, the latter being the worm.

In the figure, if OK be the radial line of any tooth, the shape of the worm tooth at an angular distance ϕ from the line of centres is such as would properly belong to a wheel whose centre of revolution was at K, and whose radius was the distance from K to the pitch circle of the wheel. K is, in fact, the instantaneous axis of the wheel which would act as a spur wheel with the worm wheel tooth *b*. Thus each part of the worm has virtually its representative instantaneous axis.

Run in an oil bath, the wheel will drive the worm if the angle be chosen fairly large. The Wilkinson tramway locomotive was an example of a worm-geared engine, in which the worm was

driven by the wheel when steam was shut off the engine. The fly of a musical box is also an example of a worm driven by a wheel. In practice worms need not be hollow-faced but simply made straight, so that the longitudinal section of a worm is a straight rack, and with involute teeth the teeth are straight sided, not curved.

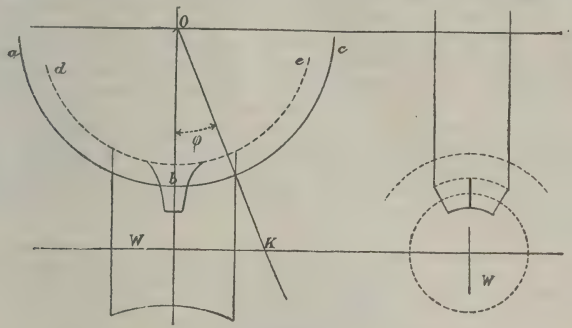

FIG. 20A.

To work at best efficiency, the angle of thread of a worm should be 45°, and it is not desirable, so far as efficiency is concerned, to employ a less angle than 30°.

High Efficiency Worm Gearing.*

Hitherto worm gears have been generally used for transmitting motion from one member to another, and usually consisted of a large wheel with a low lead angle meshing with the wheel. This resulted in low efficiencies. Of late years, however, there has been a tendency to employ machine-cut worm gearing with high lead angles, resulting in a corresponding high efficiency.

In the following observations the Globoidal type is not considered.

Pitch.—The distance from one tooth to the next, measured along the pitch line, is called 'the pitch,' and when measured along a line parallel to the axis of the worm is called the 'linear pitch.' The normal pitch is that measured normal to the thread, whilst the circular pitch is measured circularly at right angles to the axis. The circular pitch of the wheel is equal to the linear pitch of the corresponding worm.

Lead.—The distance travelled, parallel to the axis, by a thread when making one revolution round a worm is termed 'the lead,' and is equal to the number of threads multiplied by the pitch. As the thread or helix travels round and along the worm it makes an angle with the axis, or to a line parallel to it. This angle is called the 'spiral angle,' and its complement the 'lead angle.' The lead bears quite important relation to the efficiency and durability of worm gears. The maximum efficiency of a worm gear may be expressed by the equation :—

$$\eta = \frac{\tan\theta}{\tan(\theta+\mu)}; \text{ the reversed } \eta = \frac{\tan(\theta-\mu)}{\tan\theta};$$

where θ is the lead angle, and μ is the angle of coefficient of friction.

These two equations show that the maximum efficiency is obtained when the lead angle approximates 43°—40′, and that an efficiency of 50 per cent. is obtained when the worm angle is equal to the friction angle, at which point the gear is irreversible. In order to obtain a high angle, it is necessary to keep the diameter of the worm as small as possible. This also has the effect of reducing the rubbing velocity.

Influence of Speed on Pressure.—It has been stated that the permissible pressure multiplied by the velocity is practically constant. This is not so. Within the usual limits the law appears to be that the permissible pressure varies almost inversely as the cube root of the velocity. Various materials are suitable for different pressures; for light loads, at low speeds, the combination may be a cast-iron wheel and mild steel worm; for heavier loads, a cast-iron wheel and a hardened steel worm; for heavy loads, a phosphor bronze wheel and a hardened and ground worm. On the involute system engagement corresponds to a rack and spur, the revolving

* Paper read by Francis J. Bostock before the Manchester Association of Engineers.

worm causing the imaginary rack to travel along and so rotate the wheel. Therefore one has a worm whose linear or axial section corresponds to a rack, that is, each side of the worm tooth will, on the central section, be a straight line at a predetermined pressure angle. Worm gear, unless correctly designed, does not transmit a uniform velocity from one member to another. A close approximation is obtained with gears of comparatively fine pitch, and in those of a high lead angle any error is sometimes concealed by the adjacent thread being in action in such a manner that by sustaining an extra proportion of the load distribution the variable velocity period is tided over. Even the inertia of the parts may prevent a change in the velocity of the engaging pair, but this is detrimental to the gears. To consider a worm gear as a kind of a development from the screw is fundamentally wrong. The pitch surfaces of the worm gear are cylinders lying at right angles to each other, hence they only touch at one point, whereas in a screw and nut the pitch surfaces coincide. Expressed in simple language, one can say that, consistent with the transmission of uniform velocity, the normal to the surfaces from the point of contact must always cut the central plane which contains the axis of the wheel, at a point on the straight line lying on the wheel pitch cylinder, and consequently tangential to the pitch cylinder of the worm. Thus, for every point of intersection between a worm thread and the zone of contact, there is a definite relation between its angular and longitudinal positions. If contact takes place at any other point than this intersection, it does so to the detriment of the transmission of uniform velocity.

Thermal Considerations.—All frictional losses produce heat, and if the amount of heat generated be greater than the amount radiated, dissipated, or conducted away, the temperature of the gear unit will rise. When it rises above a certain point (about 250° F.), the oil film breaks down and lubricating value ceases, but they are usually run at a nice warm temperature (150° F. to 175° F.).

Thus one requires to know, in addition to the foregoing, the load factor or the proportional time the gears will run on various loads, and the thermal capacity of the case or how many B.Th.U.'s it can dissipate at various temperatures. By this data one can predetermine the temperature rise of the gear unit at the end of any period of running under a certain load factor.

Worm Milling.—Worms are usually supplied solid with their shafts and a bearing on each side of the thread. In order to guarantee concentricity and uniformity of size, a practice is made of grinding of worms on their outside diameters of the thread and journal before the cutting operation. For machining such worms special machines have been devised, and in these the worm is generally caused to travel spirally in front of the cutter, thus milling a thread space for each longitudinal travel of the table. The cutter spindle is carried in a swivelling head which enables it to be set at any angle to suit the spiral of the worm to be cut.

Cutter Form Generation.—The rotary cutter at first sight appears to be quite a straightforward matter, with its contour made to correspond with the space of the worm thread. Such, however, is far from being the case, as its actual contour is quite different from the thread space which it cuts in the worm blank, as will be seen from fig. 21 This apparent paradox

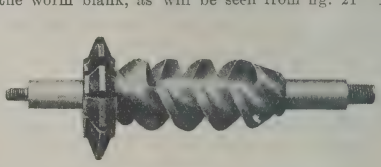

FIG. 21.—Worm and its Cutter.

is caused by the interference of the cutter with the side of the worm thread, and it will be understood when it is remembered that the worm thread is an endless spiral. As a rotary cutter must be circular in shape, and as a circle and spiral cannot coincide, it is obvious that the contour of the circular cutter cannot coincide with the thread space of the spiral worm. The base of the worm thread system is a straight line. In the system of cutter generation a straight edge tool is set to an angle corresponding to the pressure angle of the worm to be cut, and is then made to traverse in a spiral path corresponding exactly with the spiral of the worm. Thus a generating tool is mounted in a worm milling machine in the same position and manner as the worm which is to be cut, its straight edge accurately representing one side of the worm thread. When it has generated one side of a white metal blank it is indexed to the other side, thus forming the contour of the required cutter.

Hobs—Manufacture and Sharpening.—The teeth of worm wheels are of such construction that they do not lend themselves to operations of planing, shaping or milling like other forms of gearing; they can only be produced by a process of generation by means of a cutting tool called a 'hob.' Whilst it is true that the spiral angle pitch, the number of threads, and pitch diameter in the hob must correspond with that of the worm, yet both the outside and

bottom diameters of the hob are made larger in order to provide requisite clearance in the roots of the teeth. The hob throughout is gashed along its length normal to the spiral angle for the purpose of providing a cutting face, whilst the teeth are relieved in order to provide a cutting clearance. As the shape and contour of the wheel teeth are entirely dependent upon the design and accuracy of the hob, it is necessary that this tool should receive the most careful supervision in all stages of its manufacture and subsequent regrinding. Hobs are generally made with their cutting faces radial; it is therefore essential that they should be sharpened radially, or an alteration in shape will result. The same, of course, applies to ordinary rotary cutters. It will be appreciated that as a hob is sharpened its diameter is reduced, but with a reamer hob the reduction in diameter is only a few thousandths of an inch in the whole length of the teeth, thus uniformity of shape is retained.

Worm Wheel Generating.—Generally the worm wheels are rough turned on automatics and turret machines, and pass from thence to the worm wheel section for rough cutting of the teeth, after which they are finished, turned, and finally the teeth undergo a reamering or finishing operation. In no small measure is the interchangeability and high efficiency of the wheels due to this reamering operation.

The generating of the teeth of the worm wheel is carried out in a machine as illustrated in fig. 22, the blank being mounted upon a revolving table, which is positively driven at a

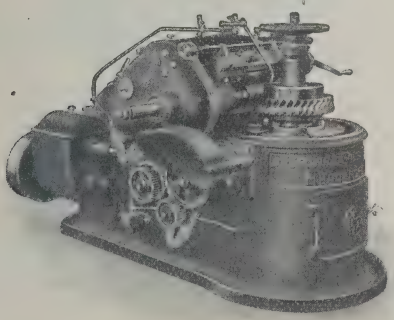

Fig. 22.—Worm Wheel Generator (*D. Brown & Sons (Huddersfield) Ltd.*).

predetermined speed, according to the ratio of the gears being cut, whilst the hob is caused to travel longitudinally across the face of the wheel. Owing to the spiral of the hob it is necessary to compensate for its longitudinal travel by means of a differential, whilst the rate of travel or feed can be varied at the will of the operator.

A special feature of the mounting of the worm wheel on the table is made. A hardened and ground micrometer adapter carries the arbor, which supports various other adapters to suit the locating register of the worm wheel blanks, the micrometer being adjusted until the specified distance from the locating face of the blank to the axis of the hob is obtained.

To facilitate setting up, and to test the true running of the registers and worm wheel blank the drive to the table is arranged so that it can be disconnected in order that the operator may be able to revolve the table by hand and so, by means of a clock indicator, test the accuracy of the mounting.

The head which slides horizontally along the bed towards the worm wheel contains the whole of the mechanism for driving the hob and traversing the hob slide. The latter is mounted on the head at an angle normal to the direction of the stress, so as to present the maximum bearing area to the very best advantage.

The main drive is taken from a single pulley fitted with an internal friction clutch in conjunction with a four-speed gear box. The drive is then transmitted in one case directly to the index change wheels for driving the table, and in the other to the worm wheel mounted on the hob spindle.

It should be mentioned that the dividing wheel is of greater diameter than the largest blank which the machine will cut, and a neat design is effected by allowing the cuttings to fall through the arms of the table into the bed of the machine, from whence the cutting lubricant is drained.

Worm and Wheel Inspection.

For testing the accuracy of the pressure angle a knife edge protractor is placed along the side of the thread and the angle read to plus or minus a few minutes. This is carried out in a worm gear testing machine, illustrated in fig. 23, which has been designed to enable the various testing operations to be performed on both worms and wheels. These can be tested separately as individual pieces, or in combination when mounted together at the specified centre distance. The bed consists of two slides at right angles, one carrying a pair of adjustable centres and the various testing appliances, whilst the other slide carries an adjustable arbor adapter, which is controlled by a micrometer screw, enabling it to be set at any required

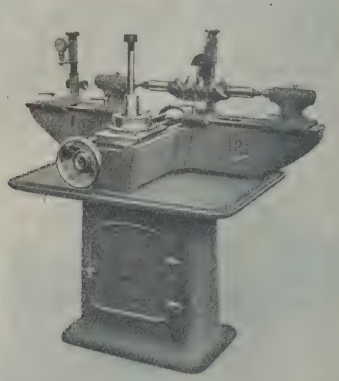

FIG. 23.—Testing Worm for Accuracy of Pressure Angle.

distance from the other slide, so giving correct centres for the worm and wheel under test. This machine is most conveniently operated, as it can be worked from either side, thus allowing the operator to be in the most advantageous position to carry out all the necessary tests. Other instruments are used on it for testing concentricity and lead.

The process of case-hardening worms is exactly the same as for other work, but although every precaution be taken some little distortion is bound to occur. They therefore require straightening so that their pitch diameter runs true; for this purpose a clock indicator on a testing machine is used in conjunction with the straightening press, and by means of a ball placed in the space this operation can be accurately and quickly performed.

Interchangeability of the worm wheel is ensured by the use of a double ball micrometer which measures the comparative pitch diameters.

The final inspection is made on a testing machine, where the gears undergo a more rigorous test. The wheels are tested for concentricity of cutting and the distance from the centre of the worm axis to the locating face, after which they are tested together to verify the centre distance.

Worm Gear Application.—Worm reducing gear units are with great advantage coupled direct to electric motors, enabling reductions in speed from 4 : 1 to 100 : 1 in a silent and efficient manner, and when both of them are mounted on the common baseplate they represent a simple, sound and economical proposition.

On account of their ability to withstand considerable overload for short periods they lend themselves admirably for intermittent work, because for the work they are called upon to do they can be made relatively small; therefore they are of great use in crane work and for starting purposes of electric motors, steam, gas and oil engines.

BEARING PRESSURES.*

Pressures on Bearings.

The following table shows the wide variation of pressure in bearings :—

	Lbs. per Sq. In.
Light and fast-running cotton spindle	2 to 5
Light shafting	80 to 100
Heavy shafting	300 to 600
Marine engine crank pins	600 to 900
Crosshead pins (horizontal engines)	1,200 to 1,300
Crank pins ,, ,,	800 to 950
Crank shaft (steam load) ,, ,,	100 to 150
,, ,, (combined load) ,, ,,	150 to 200
Second motion bearings ,, ,,	100 to 200
Crosshead slides ,, ,,	40 to 50
Intermediate piston rod slides ,, ,,	20 to 40
Main bearings (vertical high-speed engines)	200 to 300
Crank pins ,, ,,	400 to 550
Crosshead pins ,, ,,	1,000 to 1,200
Crosshead slippers ,, ,,	40 to 50
Eccentric straps ,, ,,	60 to 70
Crosshead pins (locomotive)	1,400 to 1,800
Crank pins (,,)	1,000 to 1,500
Axle bearings (loco. engine and tender)	200 to 250
Railway carriage bearings	300 to 350
Babbitt metal on cast-iron slide	200 to 250

MAXIMUM SAFE PRESSURES ON BEARINGS.

Nature of Bearing.	Safe Load. Lbs. per Sq. In.
Ordinary bearings for shafting :—	
Wrought-iron on cast-iron	250
Wrought-iron on gunmetal	300
Mild steel on cast-iron	300
Mild steel on gunmetal	370
Mild steel on white metal	500
Cast-steel on gunmetal	600
Flywheel shaft	250

At unit pressures of 250 lbs. per sq. in. for cast-iron bearings, and 145 lbs. for bronze bearings, there is difficulty in keeping the boxes from seizing the shaft.

* For Bearing Metals, see METALLURGY, Section XXXVII.

Professor W. C. Unwin carried out a series of experiments with Delta White Antifriction Metal, of which particulars are given. These tests show that this metal heats but little, even with high-bearing pressures :—

Mean Revolutions of Shaft per Minute	Mean Pressure per Square Inch of Journal Surface in lbs.	Mean Temperature in Deg. Fahr.	Mean Moment of Friction in lbs.-in.	Net Pressure on One Step in lbs.	Friction on One Step at Journal Surface in lbs.	Co-efficient of Friction

Heating of Bearings.

SIGNALS FOR INDICATING HEATING OF BEARINGS.

The double iodide of silver and mercury, $AgIHgI_2$, is a pale lemon-yellow powder at ordinary temperatures, and changes to a vivid carmine colour at about 90° to 100° C., the change in both directions being fairly sharp. The copper mercuric iodide, $Cu_2I_2 2HgI_2$, is a vivid scarlet-vermilion at ordinary temperatures, and at 60° to 70° C. it changes to a chocolate-brown. Both these compounds are adapted for use under suitable conditions, but a mixture of the two, consisting of 85 per cent. of the copper salt and 15 per cent. of the silver salt, is more sensitive and gives a greater colour range from vermilion to almost black, the transition being exceedingly sharp.

The compounds may be prepared in a variety of ways. A simple method of preparing the copper salt is by well triturating in a mortar 380 grms. of cuprous iodide with 910 grms. of mercuric iodide, sufficient water being added to form a paste. When thoroughly mixed, the mass is dried in the water-oven, and the dried mass ground to an impalpable powder. Another method is to dissolve the mercuric iodide in excess of potassium-iodide solution, and precipitate the double salt by the addition of copper-sulphate solution. The silver salt can be prepared in a similar manner by double precipitation. Whichever method is adopted the product should be well washed to eliminate soluble impurities, as these appear to retard the colour-change, as well as to affect its character.

To apply the mixture, convert it into a varnish paint or enamel, by incorporating the powder with a colourless varnish medium that will stand moderately high temperatures without softening. A good white-shellac spirit-varnish, such as is used on electrical machinery, has been found suitable for most occasions, but for high temperatures a medium such as is employed in the high-temperature aluminium paints used for steampipes, and which will resist temperatures up to 200° C., is preferable. About 100 grms. of compound to 70 c.c. of medium will be found a mixture of suitable consistence.

A convenient method of applying this heat-detector is first to paint a white circle or ring on the bearing or other place which it is desired to keep under observation, using a zinc-white paint. This white circle is applied to the journal or housing of the bearing, and the detector-paint is applied as a vivid red bull's-eye in the middle of this, thus forming a striking object which is visible from considerable distances. It must be applied to the block of metal as near as possible to the point at which the heat is likely to be generated. It is sometimes desirable to apply the paint to the shaft itself, just where the latter extends beyond the bearing-metal. A convenient method is to apply a broad band of white paint with a narrower band of the red detector paint in the middle. This red band in the middle of the white one is easily seen as the shaft rotates. In any case, after the paint is dry it should be protected with a coat of colourless oil-proof varnish, so that the surface may be occasionally wiped free from dust and dirt. The visibility of the paint against its white background is high, the bright scarlet colour being visible from long distances without effort, and the change at 60° to 70° C. to black is easily observed. It is generally easy to arrange matters so that the detector is placed in a position where it is visible almost without conscious effort; and experience has proved that a workman is easily trained to cast his eye occasionally on the detector, while he could not be depended upon to climb to the spot and feel the bearing on the remote chance of finding it heating. When the paint changes colour there is something wrong with the bearing, but generally speaking it will be found that the matter is taken in time, and that no damage is done, the bearing simply requiring cleaning and adjustment without serious stoppage and expense. *(H. T. Pinnock, 'Journal of the Chemical Society.')*

BALL AND ROLLER BEARINGS.

(Contributed by Professor John Goodman, M.Inst.C.E., M.I.Mech.E.)

Ball Bearings.

In the earliest cylindrical or radial bearings the balls bore on four points as shown at A, fig. 1,* and corresponding thrust bearings were made, as shown at F. It is impossible, under such conditions, to secure a pure rolling motion for the balls, so that grinding inevitably takes place. The modification shown at G was then tried, but only with partial success. Three-point bearings, such as those shown at B, C and H, and also many others, were tried, but in every instance the balls grated and developed deep scratches after running for a short time; they were then

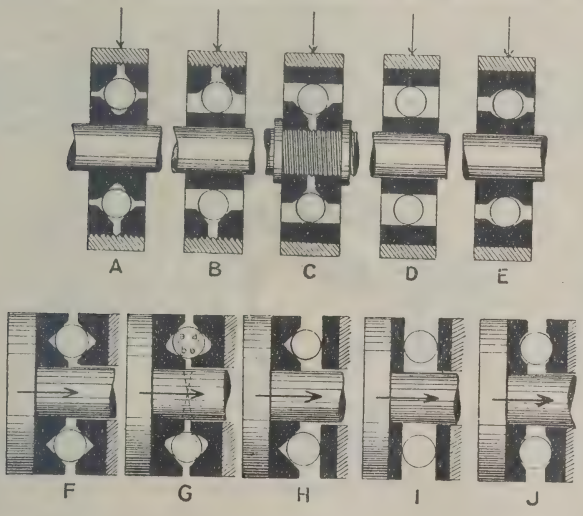

FIG. 1.

* Figs. 1, 6, and 8 are reproduced from Professor Goodman's 'Mechanics applied to Engineering,' by the permission of the publishers, Messrs. Longmans, Green & Co.

abandoned for two-point bearings (the outcome of experiments by the writer), shown in D and I. The friction was found to be less, the bearing was cheaper to make, the balls had a true rolling motion, and, consequently, showed no signs of scratching, grinding, or wear; the bearings ran smoothly, and were in every respect a success. In general, a cage was used for keeping the

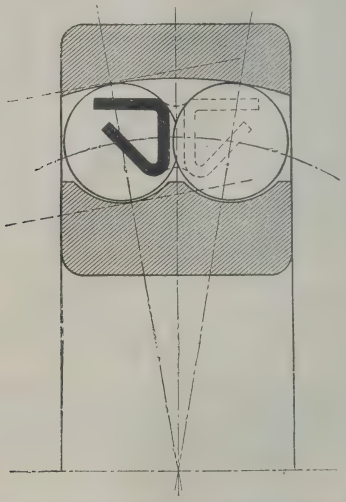

FIG. 2.—Diagram showing Construction of 'Skefko' Radial Ball Bearing.

balls in their relative positions, but in some instances it was found that it might be dispensed with. Other experimenters, notably Professor Stribeck, of Berlin, modified the two-point bearing by providing grooved ball races, as shown in E and J. Balls running in such races will support considerably greater loads than when running on plain surfaces which, of course, is a great advantage. The load that may be placed on a bearing of given dimensions, other

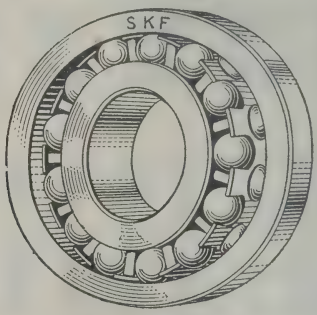

FIG. 3.—Radial Bearing.

things being equal, depends on the number of balls interposed between the races. In the bearing D there is no difficulty in inserting the full number of balls, but in the bearing E not much more than one-half the full number of balls can be inserted unless a transverse groove is cut in the side of each race through which the balls may be sprung or some other device

adopted. The difficulty of inserting the balls is overcome in a most ingenious manner in the 'Skefko' bearing, by making the inner surface of the outer ball race a portion of a sphere the centre of which coincides with the centre of the shaft. By tilting the cage and inner race two full rows of balls can be inserted. See figs. 2 and 3.

The quality of the steel for the balls and races must be of the best, and the amount of carbon should approach the saturation point, viz. 0·89 per cent. Some makers of repute prefer chrome steel. The hardening and tempering must be done with the greatest possible care.

The amount a ball yields when compressed is very small, hence it is of the highest importance

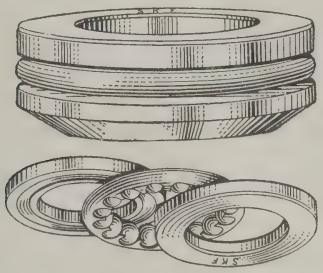

FIG. 4.—Single-thrust Bearing.

that the balls should be as nearly spherical as possible, and that all the balls in a given bearing should be of exactly the same size; also that the races be ground and polished to a high degree of accuracy. A defect of $\frac{1}{10000}$ inch is fatal to smoothness of running and to the life of a bearing. All makers of repute will now supply balls guaranteed to be correct to within $\frac{1}{100000}$ inch.

A ball bearing must be truly mounted on its shaft in such a manner that it will not shift and yet it must not be so tight as to unduly expand the inner race. The outer race must be a good sliding fit with a small amount of end play in its housing. The most perfect ball bearing may easily be ruined by unskilful mounting; indeed, it is practically certain that nearly all

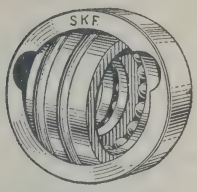

FIG. 5.—Self-contained Double-thrust Bearing.

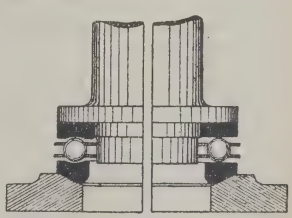

FIG. 6.

failures of ball bearings can be traced to this cause. Users who are not in the habit of working to $\frac{1}{10000}$ inch will do well to send their housings and shafts to the makers in order to have the ball bearings accurately fitted. Owing to the spherical seat in the 'Skefko' bearing, the shaft may be allowed to run considerably out of truth without seriously affecting the smoothness of running of the bearing.

It is of the highest importance that ball bearings should be kept free from dust and grit.

In the case of thrust bearings, the stationary ring should always be made with a spherical seat to allow the bearing to align itself in the event of the centre line of the shaft getting shifted relatively to the housing. See figs. 4, 5, 6.

Permissible Loads on Bearings.

The safe working load for a given bearing is much greater when the bearing is running at a low than at a high speed. The ruling factor as regards the working load for a ball bearing is the speed of rotation of the balls themselves; thus in the case of two shafts, A and B, each fitted with thrust bearings having the same number and diameter of balls, and both running at the same number of revolutions per minute, if the diameter of the ball path in A were greater than in B, the safe working load would be greater for shaft B than for A.

Let P = The maximum permissible working load in pounds.
d = The diameter of the ball in inches.
D = The diameter of the ball path in inches.
n = The number of revolutions per minute of the shaft.
k = A constant depending upon the form of bearing.
c = A constant.
m = The number of balls in the bearing.
x = A coefficient depending upon the revolutions per minute of the shaft.

Stribeck's formula for radial ball bearings is :—

$$P = 12{\cdot}8\ x\ m\ d^2$$

where x has the following values :—

n 0	10	150	300	500	1,000	1,200
x 48·4	36·3	29·04	24·2	20·9	15·62	14·96
n 1,500	2,000	2,500	3,000	4,000	5,000	10,000
x 13·64	12·1	10·56	9·68	8·58	7·7	5·06

Goodman's formula for ball bearings is :—

$$P = \frac{k\ m\ d^3}{nD + cd}$$

where k and c have the following values :—

Type of Bearing.		k	c
Radial.	Flat (i.e. not grooved) races	1,000,000	2,000
	Hollow races of ordinary quality	2,000,000	2,000
	Hollow races of best quality	2,500,000	2,000
Thrust.	Flat (i.e. not grooved) races	500,000	200
	Hollow races of ordinary quality	1,000,000	200
	Hollow races of best quality	1,250,000	200

A comparison of the results obtained by the two formulæ is shown in fig. 7.

In the 'Skefko' bearing the races must be regarded as flat, but since there are at least twice as many balls in this type of bearing as in other bearings of the same external dimensions, the theoretical load carrying capacity is the same. It is claimed that this bearing will work satisfactorily with a small amount of lateral thrust.

Design of Ball Bearings for Big Loads.

When a ball bearing is required for a load larger than that given in makers' catalogues, a special bearing can be designed and made to suit the conditions, but any departure from the makers' standard sizes is a costly proceeding. It is always less expensive, and generally much more satisfactory, to use multiple ring bearings consisting of two or more standard commercial

bearings suitably mounted. The difficulty when using multiple ring bearings is to ensure that the load shall be evenly distributed over all the rings. Goodman overcomes this difficulty by

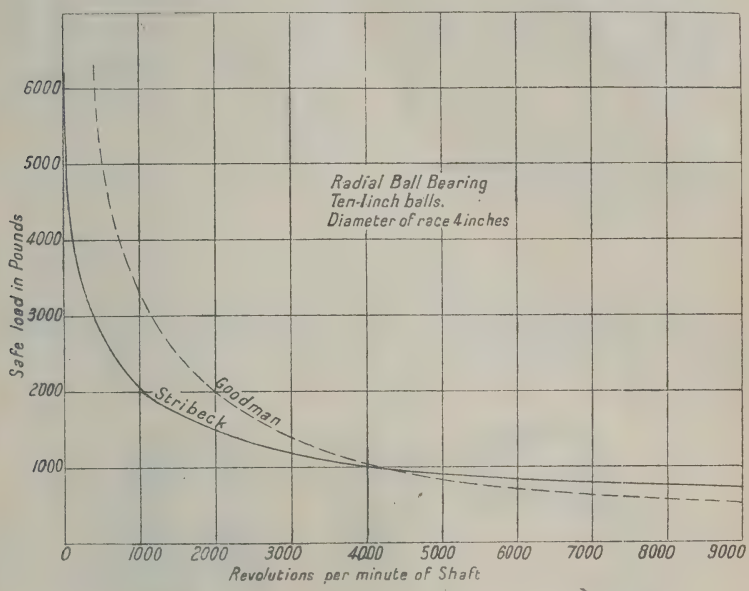

FIG. 7.

backing them with linoleum as shown in figs. 8 and 9.* The housing must also be spherically mounted in order to allow it to adjust itself to any want of alignment.

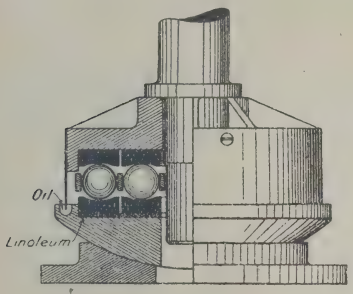

FIG. 8.

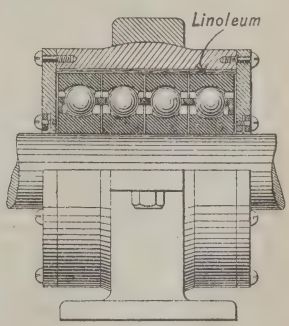

FIG. 9.

* Figs. 9 and 10 are reproduced from the Author's paper on 'Roller and Ball Bearings.' Proceedings of the Institution of Civil Engineers, by the permission of the Council.

Advantages and Disadvantages of Ball Bearings.

Advantages.

The friction is usually less than one-tenth of that encountered in ordinary bearings as commonly lubricated.

The friction at starting is no greater than when running.

The friction does not increase with the speed.

They require an extremely small amount of oil, the cost of which is negligible.

They occupy much less lateral space on the shaft than an ordinary bearing.

If the bearing is properly treated the wear is extremely small.

Disadvantages.

The first cost is usually greater than that of an ordinary bearing, but this is not invariably the case.

If overloaded, or if lubricated with unsuitable oil the balls pit and peel, and then they make a great deal of noise, especially at high speeds.

They require extreme care in fitting on to the shaft and in the housing.

Roller Bearings.

A great many attempts have been made at producing a satisfactory roller bearing for big loads, but with the exception of one or two well-known types of roller bearings they have only met with indifferent success, mainly owing to the fact that the rollers tend to creep endwise along the shaft, and thereby produce 'end thrust' on the cage and casing. The cause of the trouble is perfectly well known; it has been successfully overcome by several makers, although exceedingly difficult to remedy. In the early days of roller bearings it was believed that the

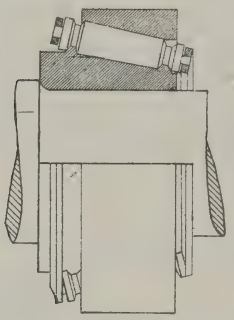

Fig. 10.

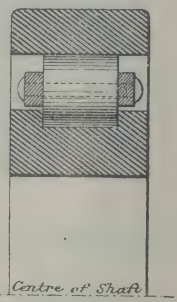

Fig. 11.

trouble arose largely from imperfect workmanship, and very costly experimental bearings made of excellent materials, and with a marvellous degree of accuracy, were tried with variable success. The Hyatt bearing, in which the solid rollers are replaced by helical springs arranged alternately with right- and left-handed helices, has been designed to meet this difficulty, whilst the Empire Co. has also introduced improvements which are claimed to overcome the trouble. A high duty type of bearing has recently been introduced in which the roller and races are hardened and accurately ground.

Other makes which claim to run satisfactorily under high loads per square inch bearing surface are those in which short rollers are used, the rollers and races being made of the best quality of glass hardened tool steel, finished and ground to as high a degree of accuracy as a high-grade ball bearing. The rollers in such bearings are always kept in their correct position by means of a suitable cage. A bearing of this type—the Timken, fig. 10—is largely used for motor-car work; owing to the rollers being tapered, wear can be taken up if necessary. Another highly finished roller bearing of this type—the Hoffmann—is shown in fig. 11, the end thrust is very small, the friction is no higher than in the best ball bearings, the load-carrying capacity is greater than that of a ball bearing of the same general dimensions, and the wear is practically nil, even when the bearings are allowed to run for years under considerable overloads.

Even the most perfect roller bearings will fail if they are not carefully mounted and kept free from grit.

Lubrication of Ball and Roller Bearings.

All well designed ball and roller bearings will run for long periods, and quite satisfactorily, without any lubricant if they can be kept perfectly free from dust, grit, and moisture; but since such conditions can rarely, if ever, be fulfilled in practice, some lubricant must be used, which should be most carefully selected. An unsuitable lubricant may ruin a bearing in a few weeks. Lard oil of the best quality gives good results, but some prefer a semi-fluid lubricant, such as Duckham's or Nicol's grease. The amount used is exceedingly small as compared with an ordinary bearing, hence it is the height of folly to run the risk of ruining a bearing by using a cheap, but unsuitable lubricant.

Sternol Ball-bearing Grease.

(Sterns Ltd.)

This is guaranteed by its makers to be an absolutely pure neutral grease, specially manufactured for use in ball bearings. It is certified by the Sheffield Testing Station, and recommended by leading ball bearing manufacturers.

Thrust Bearings.

A considerable number of thrust bearings have been recently made which have a mechanical efficiency quite as high as a modern journal bearing, combined with the same high load-carrying capacity. At the rubbing speeds usually obtained in bearings the coefficient of friction for smooth dry surfaces ranges from 0·06 for some anti-friction metals, and steel to about 0·15 for cast-iron and steel, but when the surfaces are properly lubricated the coefficient may fall to 0·0012 or less. This figure is commonly obtained in the better class of journal bearings. An equally low frictional loss may be secured in thrust bearings. Fig. 12 shows a pivot thrust

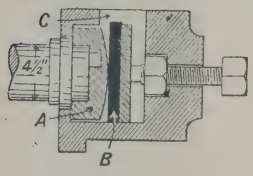

Fig. 12.

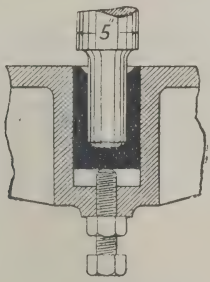

Fig. 13.

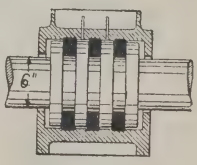

Fig. 14.

bearing as sometimes used in the worm shaft of a brick-making machine. The end of the shaft is fitted with a steel shoe A which is thrust against the gun-metal plate B. The box C is filled with grease. The pressure when the plate B is new is very high, and when worn hollow is about 1,200 lbs. per sq. in. The high pressure squeezes the grease out. A bearing of this type is very inefficient.

Fig. 13 shows an ordinary footstep bearing as used in some water turbines. The load is usually about 1,000 lbs. per sq. in., under which pressure efficient lubrication is impracticable, with the result that there is metal-to-metal contact, a high coefficient of friction, wear is rapid and ample adjustment must be provided.

Fig. 14 shows a section of an ordinary collar thrust bearing. Owing to the large radius of friction, the coefficient of friction must be kept low if this type of bearing is to be reasonably efficient. This is accomplished by increasing the number of collars on the shaft so that the area is increased, and the pressure thereby reduced to 50 or 60 lbs. per sq. in. At such a pressure the oil can find its way between the collar faces, and the coefficient of friction under such circumstances is about 0·03. According to Mr. Beauchamp Tower, a pressure of 75 lbs. per sq. in. is the maximum that can be safely carried under such conditions.

The following comparison shows the inefficiency of the pivot and collar thrust bearing, as compared with a perfectly lubricated journal:—

Type.	Lbs. per Sq. In.	Average Friction Coefficient.	Condition of Surface.
Pivot thrust . .	1,000 to 1,200	0·10	Dry.
Collar thrust . .	50 to 60	0·03	Greasy.
Journal bearing . .	500 to 600	0·0025	Perfect lubrication.

Mr. Tower found that for journal bearing with oil-bath lubrication a load of 600 lbs. per sq. in. could be carried with safety, but when the oil was supplied from the top by a hole drilled through the brass, and an oil groove cut along the under surface, heating resulted with a load of 100 lbs. A film of lubricant between the surfaces is the object to be aimed at. A thrust bearing made with one plane surface subdivided into radially arranged segmental blocks each pivoted in the

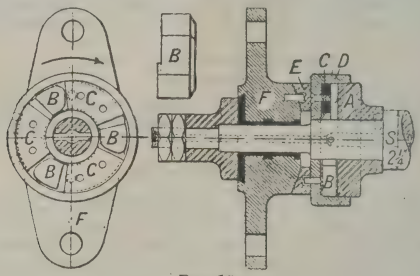

FIG. 15.

vicinity of the resultant pressure and free to move through a slight angle from the plane of rotation, will approach the efficiency of a perfectly lubricated journal when plenty of oil is provided.

The permissible pressure on these bearings is proportional to the speed and viscosity of the lubricant. If a bearing can carry 50 lbs. per sq. in. at a speed of 1 foot per second with an oil of 0·5 viscosity, it will carry 500 lbs. with an oil of 5·0 viscosity at the same speed, or at a speed of 10 feet per second with the same oil. These bearings are employed in high-speed turbines with oil lubrication, and for slow speeds in grinding machinery with grease lubrication.

A steam turbine thrust bearing of this type, made by Belliss & Morcom, of Birmingham, to the design of Mr. H. T. Newbigin, is shown in fig. 15.

A is the collar on the shaft, B are the segmental rubbing blocks, the backs of which are cut away as shown to allow of their tipping through the necessary angle to the plane of rotation

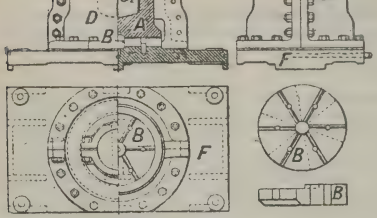

FIG. 16.

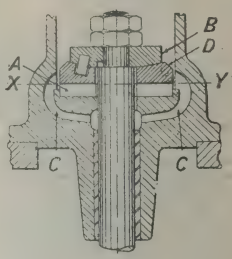

FIG. 17.

C are spacing blocks between which the loose rubbing blocks are fitted. The casing D holds the spacing and rubbing blocks together. Automatic adjustment is provided by the concaved face of the washer E, and convex face of the cross-piece F, which is bolted to the turbine frame. The oil is supplied through the hole in the centre of the shaft S. The bearing was tested under a load of 1,500 lbs. or 500 lbs. per sq. in. at a speed of 1,750 r.p.m., under which it ran continuously at a temperature of 126° F. The oil used had a viscosity of 4·6, and with a thinner oil would probably have run at a lower temperature.

A low-speed bearing of the Mitchell type (see Index), designed by Mr. Newbigin for the large pan grinding mills of T. C. Fawcet, Ltd., of Leeds, is shown in fig. 16. There is no spherical adjustment, but the shaft is a loose fit in the shoe-piece A, which is turned by a driver G attached

to the shaft; there are no spacing blocks. As in fig. 15, B are the segmental blocks, D the casing, and F the cross-piece. This bearing is designed for a load of 13 tons, or 350 lbs. per sq. in. of bearing surface, and a speed of 24 r.p.m. It required about $1\frac{1}{2}$ oz. of thick grease per day.

Fig. 17 shows a further development of the Michell invention, and is lubricated with water only. The speed is about 2,800 r.p.m., and the load 150 lbs. The rubbing surfaces consist of three small blocks marked A, cut away at the back to allow them to tilt and draw in the lubricant, and each pivoted behind its centre in the direction of rotation. Automatic adjustment is provided for by the spherical seat, and water circulation through the ports C. The blocks A automatically tilt relatively to D, and thereby maintain hydraulic pressure between the surfaces and prevent metallic contact. (*H. T. Newbigin, Inst. of Civil Engineers.*)

According to Reuleaux the maximum pressures (lbs. per sq. in.) for pivot bearings are :—

Wrought iron on lignum vitæ, $p = 1{,}400$ lbs.; wrought iron on gunmetal, $p = 700$ lbs. cast iron on gunmetal, $p = 470$ lbs.

Compared with practice these pressures are suitable for speeds below 10 ft. per minute. For a speed of 20 feet take $\frac{1}{4}$, 50 feet take $\frac{1}{8}$, and 100 feet take $\frac{1}{5}$ the maximum values given.

SECTION XIX

PART II

LUBRICATION AND LUBRICATORS

(Revised by Prof. John Goodman, M.I.C.E., M.I.Mech.E.)

LUBRICATION

Steam Cylinders.

The use of fatty matter, however desirable it may be from the frictional point of view, is controlled by consideration of the destination of the steam after it leaves the cylinder. If the spent steam exhausts into the atmosphere, or if it is condensed by a spray injection and subsequently run into a pond or lodge into which the oil, carried over with the steam, may separate from the water by floating on the surface, it is permissible to use compound oils. But if the condenser is of the surface tubular type, in which the steam is condensed and, without the addition of fresh water, is returned to the boiler with any oil which it carries with it, fatty oils must be avoided, and care ought to be taken in the selection of the hydrocarbon oils to be used.

Gas and Oil Engine Cylinders.

While in the case of some steam-engine cylinders fatty oils are dangerous and ought to be avoided, their use in the cylinders of internal combustion engines is almost as important for successful working as it is objectionable in steam cylinders. This difference in steam-engines is due to the destructive effect of steam with the elements of water and high temperature upon fats, while in the internal combustion engine these conditions, and the free oxygen required for the formation of acids, are absent, and fatty oils, either pure or blended with hydrocarbons, are found to give the best results in respect to efficiency and to prevent the formation of gummy deposits in cylinders and valves.

Crank Chambers.

In engines of the Willans type, in which lubrication is effected by a bath of water with a thin layer of oil on the top, it is generally safer to use a pure hydrocarbon of good body, preferably of the charcoal refined class, which represents the highest lubricative efficiency obtainable in mineral oil. It is important that the oil selected, especially if it is to be used in conjunction with hard water, should be free from tendency to emulsify, as, should this occur in the crank case, lubrication will be much impaired.

For engines lubricated by force, as in the Belliss and some others, an oil of moderate body is required, as, assuming that the bearings are in good condition, the pressure of the pump ought to provide a continual film of oil on each journal. It is also important that this oil should separate freely from water, as the formation of an emulsified magma would interfere with the circulation of the oil.

Crankshaft Bearings.

It is impossible to lay down definite rules in regard to the oil to be used on these bearings which vary greatly in size, in speed, and in the method of applying the oil. Speaking generally, for large engines, lubricated by syphons or by pipes, a pure fatty oil, or an oil of good body containing an important percentage of fatty oil, ought to be used. It is important to note, in comparing a fatty oil with a mineral oil, that their respective efficiency cannot be determined by body or viscosity alone, as, on account of some hidden virtue in fatty oils, it will be found that a fatty oil of moderate body will reduce friction to a greater extent and will last longer than a mineral oil of much superior body, showing that body by itself is not the final criterion.

Ring Lubrication

introduces another condition apart from the direct question of the immediate efficiency of the oil. In ordinary lubrication the oil is slowly fed to the bearing at a rate calculated to make good the loss by waste or use. The oil, therefore, practically serves only once, but in the case of ring lubrication the oil may remain in use for months with only occasional slight additions to replace waste; but during all the time that the oil is in use it is being taken up by the rings and spread over the journal and bearing in a thin film continually exposed to the action of the atmosphere. Under these conditions an animal or vegetable oil would, by the absorption of oxygen from the atmosphere, be slowly thickened and become gummy and unsuitable. Therefore, in this case, it is advisable to forgo the advantages offered by fatty oils and to select a pure hydrocarbon oil of suitable body and high boiling point which will not too readily lose bulk by evaporation or be chemically affected by the action of the atmosphere.

Note on Ring Lubrication.

Sluggish action of the oil-rings of motors in a large New Jersey factory, leading to improper lubrication of the bearings, was cured by bevelling the sides of the rings. On testing the motors it was noticed that the rings would creep along at a very slow speed, two or three revolutions a minute on a machine of several horse-power, instead of the regular speed of about thirty to fifty revolutions. It was finally discovered that under certain conditions a ring would start with the machine and perhaps come up to normal speed, but would soon work itself towards one side of the slot and slow down, hugging closer and closer until there was only a very thin film of oil between the ring and the flat part of the journal.

Three rings were removed and their sides were slightly bevelled, when the trouble entirely disappeared. (*P. G. Bernholz, 'Electrical World.'*)

Turbines.

The only parts calling for lubrication in turbines are the glands and the external bearings. In the larger sizes both the glands and the bearings are provided with jackets through which water may be circulated, when this is necessary, to keep the bearings cool. In the earlier types of turbines, the glands were packed in the ordinary manner and called for the use of oil of a cylinder character to reduce friction. In modern practice the glands do not call for lubrication, as they are fitted with special metallic ring packing which does not make metallic contact with the shaft. A little water is injected and serves to condense any escaping steam at the high pressure end and the admission of air at the low pressure, or vacuum, end and also in a measure acts as a lubricant. The lubrication of turbine bearings is usually effected by the circulation of oil by a pump which forces the oil from a tank in the base of the engine through a system of pipes to the bearings, from which it returns by other pipes to the tank through which cold water circulates in pipes to reduce the temperature of the oil.

The conditions calling for consideration in the lubrication of turbines seem to be the abnormally high temperature of the bearings, due to the transmission of heat by the shaft from the turbine, the probability that, despite most careful precautions, water may find its way into the oil, and the fact that the oil may remain in use for many months without change and with comparatively little addition of fresh oil. These conditions call for oil of considerable body, which should not be liable to emulsify in contact with water, and which should not be injuriously affected by long use and contact with air. (See also page 1570.)

Dynamos,

which are generally provided with ring bearings, should be dealt with on the lines indicated in 'Ring Lubrication.'

Air Compressor Lubrication.

See page 1083.

COOLS HEATED BEARINGS

COOLORICID COOLS HEATED BEARINGS IN THE MODERN & EFFICIENT WAY

A single application of Cooloricid and the bearings instantly become cool. No need to risk seizure or fraction by running on. No need to stand your machinery idle, paying high wages and getting nothing in return. Just one application of Cooloricid—that's all.

STERNOL

Packed in 56 and 112 lb. drums. Price 2/6 per lb. Delivered Carriage Paid—United Kingdom. Package Free.

STERNS LIMITED

127 Royal London House, Finsbury Square, E.C. 2.

FOR DRILLING, CUTTING, BORING AND TURNING.

SUPER-SCREWOL

SUPER-SCREWOL is too good to remain unknown or untried by you. For drilling, cutting, boring and turning it has no equal. It does not clog or separate. It preserves the life of the tool, increases output, and is antiseptic to government standard.

On receipt of a request on your note heading, we will forward, carriage paid, a barrel of Super-Screwol. You will be at liberty to test it completely. Should you then decide not to use the remainder, you can send it back at OUR cost, and we will charge nothing at all for the quantity used.

STERNS LIMITED

127 Royal London House, Finsbury Square, E.C. 2.

Shafting.

requires oil of moderate body, which may be either a compound oil, if the best results are required, or a pure mineral oil if the strain on the bearings is not too great and the system of lubrication ensures a constant and regular supply of oil.

Abrasive Wheels.

See page 1006.

Automatic Tools.

The high speeds adopted in tools of the turret lathe type, and the great pressure and high temperature developed at the cutting point in large automatic lathes, call for oils of superior quality to save the edge of the tool and the surface of the metal on which it operates; but although the old-fashioned soap-suds are unsuitable, from their rusting action on the tools and on the metal of the job, it has been found that, in many cases, satisfactory results are, and may be, obtained by the use of a soluble oil, or soluble paste dissolved in water, which keeps the cutters cool and in good condition, and does not rust the job.

See also page 993

Drills.

See pages 957, 994.

Graphite Lubrication.

Graphite, plumbago, and blacklead are mineralogically similar, but whereas blacklead often consists of a large proportion of clay and very little pure blacklead, on the other hand graphite (especially those grades prepared for very special lubricative purposes) may consist of as much as, and even more than, 99 per cent. of pure graphitic carbon.

The selection and preparation of graphite for lubrication requires the observance of two principal considerations, viz., the structure of the graphite itself and the character and amount of other matter incorporated with it. For instance, a flake graphite, comprising 95 per cent. of pure graphitic carbon having the necessary unctuousness, but mixed with 5 per cent. of hard siliceous rock or quartz, would not be satisfactory for any form of lubrication. Unfortunately, many purchases of such deleterious admixtures are made because the price is lower than, for example, a flake graphite, consisting also of 95 per cent. unctuous graphite with 5 per cent. smooth foliated micaceous matter. The latter, for many purposes, is every bit as good as a 99·8 per cent. or 99·9 per cent. pure flake graphite, and is comparatively much cheaper than grades of such high purity, but its cash value is many times that of the one containing rock or quartz (though the difference in actual cost between the 'quartz' grade and the 'soft mica' grade may only be a few pence per lb.). The damage which such an abrasive mixture will undoubtedly do to any kind of machinery is serious. Engineers should therefore exercise very particular supervision over these purchases.

As already stated the important points are :—

(1) The structure of the graphite, and (2) the character and amount of the impurities in it.

Flake graphite is necessarily the best for lubrication, when consideration is given to the manner in which its lubricative duties are performed. It is required to associate itself and become attached to, and form part of, one or both of the rubbing surfaces, and impart an even and smooth finish to these surfaces, by filling up any tiny depressions. The way confetti clings to the floor is a good illustration in this connection of the advantage of a flat or flake structure.

In the well-known 'Foliac' brand of flake graphite (of *Graphite Products, Ltd.*), the flake structure is combined with foliations which act similarly to a pack of cards under pressure, by slithering apart and presenting a much larger smooth and slippery surface. This foliated or laminated structure is a distinct feature of these products, and it is claimed that a much lower coefficient of friction is obtained with them than with, e.g., the amorphous varieties of graphite or plumbago, whether carried to the surface in colloidal form or not. In connection with colloidal or deflocculated graphites it must be remembered that acidity, alkalinity, or other disturbing cause is necessary in order that the colloid may flocculate into particles large enough to attach themselves to bearing surfaces.

Recent investigations have shown that representative samples of 'Foliac' flake graphites gave the following results :—

Foliac No. 1,	assayed,	92·00	per cent. carbon.
Foliac No. 2,	,,	95·50	,, ,,
Foliac No. B1371,	,,	96·13	,, ,,
Foliac No. 100,	,,	99·85	,, ,,
Foliac No. 101,	,,	99·75	,, ,,

Because graphite has a higher specific gravity than oils (about 2·2 to say ·9 or so for oil) it is impossible to permanently suspend it in ordinary lubricating oils, at any rate without special

and complicated treatment; therefore, in order to convey flake lubricating graphites to bearing surfaces with certainty and regularity, suitable greases with the graphite in intimate admixture are best. Many instances are recorded where suitable flake graphite greases have outlasted other kinds (without flake graphite) five or six times and with less friction.

The Use of Graphite.

The right kind should be selected for a specific purpose. As examples, the large flake is best suited to large areas of surface, whether bearings, cylinders or valve faces; and the small flake is best for smaller areas of surface. At the same time, for intricate, fine or fast moving motions, it is well to select a specially prepared fine flake graphite for these purposes.

All surfaces in frictional contact should be well rubbed with the selected flake graphite for any particular class of machinery, before assembly. This rubbing is best done by dipping a clean oily pad in the graphite, and rubbing it well into the surfaces. The smoothness and consequent reduction of friction is most noticeable, and it is a very long time before this 'graphite skin' or polish is lost.

The removal of the flake graphite after this rubbing in can only be done by filing or grinding—in other words, to remove it, the surface of the metal itself has to be removed.

For regular use after assembly of parts, as already stated, one of the flake graphite greases is best, but occasional doses of flake graphite can be fed with the ordinary lubricating oil with most satisfactory results. It will be obvious that the large flake graphite mixed with a thin spindle oil will settle much faster than a very fine flake graphite in a bodied engine or heavy machine oil.

Too much should never be used, especially when mixed with oils—from 2 per cent. to 5 per cent., according to the service required, is usually ample. With greases, the proportion may be larger.

Graphite, particularly the flake variety (if free from abrasive matter), is an exceedingly useful and beneficial product—but it should not be used to excess, as too much is likely to give trouble.

Feeding Graphite.

In the first place, when erecting or repairing engines, or whenever the cylinders and valves are opened, the working surfaces should be freely covered with a thick mixture of graphite and cylinder oil. Flake graphite cannot satisfactorily be fed through the usual sight-feed displacement lubricators for the reason that its high specific gravity causes it to settle in the oil and to clog up the connecting pipe. A reasonable doubt might be entertained as to whether graphite can readily become attached to the frictional surface if it is so fine that it passes through the pores of filter paper, as is claimed by some, which would indicate that the particles of graphite are surrounded by an unbreakable oil film. But if these particles could become attached to the frictional surface, efficient but not lasting aid to lubrication would certainly result. Experience seems to show that there is a limit to a desirable subdivision of graphite, and if this is so the settling of graphite in cylinder lubricators must be overcome by mechanical means, since even the smallest particles of graphite which can be seen will settle in oil. There are, however, cylinder lubricators on the market for feeding graphite, the best-known of which relies on continuous stirring to secure suspension of the graphite, even in the delivery pipe, by means of a spiral wire which is constantly turning.

Graphite as a Lubricant for Cylinders.

As a cylinder lubricant, flake graphite has come to be widely used, as it is quite unaffected, either chemically or physically, by any temperature encountered in a cylinder, and retains its high lubricating value even when at a red heat.

Wells and Scott-Taggart, in their book 'Cylinder Oil and Cylinder Lubrication,' write concerning the oil polish as follows: 'In order to satisfy themselves as to the working of an oil, most engineers open the cylinders at intervals and note the condition of the surfaces. Satisfaction is generally felt if they find the inside of the cylinder polished like silver, or if it has a bright, smooth surface, "like a mirror," as some express it. Now, this is not by any means the condition the cylinder ought to be in, if it is lubricated with oil alone. Suppose an engineer found, on opening the cylinders of his engine, that bright streaks existed, he would conclude at once that the bright spots were the result of friction . . Strange to say, if he found the whole surface of his cylinder polished, he would not think it was friction. A well-lubricated cylinder ought to present a rather dark-looking surface, smooth, but with no signs of bright polish, even if coated with oil. The slightest rubbing with a polishing rag would produce a bright surface on such a cylinder, thereby proving that the lack of a polish is due to the absence of friction.'

In addition to the 'oil polish' referred to above, there is the smoothing and polishing effect produced in ammonia cylinders of refrigerating machinery, the 'water polish' frequently observed in marine engines and in pump cylinders, and the 'graphite polish.' This last is different

from the others, which are really friction polishes, obtained by rubbing off the roughnesses of the grain of the metal. Graphite polishes by filling in the grain of the metal, just as wood filler and varnish polish a surface of wood, and cannot therefore be construed as an evidence of friction.

The question of the best manner of separating graphite from exhaust steam is frequently raised by those not familiar with its use. In answer it may be said that any separator, grease extractor, or settling tank that will remove even a fair percentage of cylinder oil will remove all the graphite that goes out with the exhaust. Graphite passing into a separator is apt to adhere to the baffle plates, and it is good practice to remove and clean them from time to time.

Where measures are not taken to separate or otherwise eliminate such graphite as may leave the cylinder with the exhaust steam, certain small amounts may pass into the boiler with the feed water. Graphite in a boiler is an advantage rather than a detriment. If the feed water contains scale-forming salts, the graphite will combine with the scale to make it softer and more easily crumbled. The heat transfer will not be affected, for graphite is a very good conductor of heat. (See also Foliac Boiler Graphite, page 1441.)

Graphite as a Lubricant for Gas Engines.

An authority on gas-engine cylinder lubrication has stated that the perfect lubricant for this work should either be consumed entirely or else not at all. Flake graphite meets this last requirement fully, since the intense heat encountered in a gas-engine cylinder has no effect whatever on graphite. There are many ways of feeding graphite for gas-engine cylinders, as there are many types of gas engines, but space does not admit of a full description of the different methods. Inhalation of dry graphite from a closed container or cup attached to the inlet pipe into the gas and air mixing chamber has been successful, the pulsations due to alternate compression and reduction of pressure allowing a little graphite to feed through the hole (say $\frac{3}{32}$ in. diameter) in the bottom of the container.

Difficulty has sometimes been encountered with graphite by its short-circuiting sparking points in jump-spark ignition. This usually means that too much graphite has been used, and reducing the quantity removes the trouble.

'Sternoline' Bricks for Lubrication of Bearings.

(*Sterns Ltd.*)

These bricks are of solid oil, and form a high class lubricant for open and tunnel bearings. They are free from acid, impurities or dirt, are non-corrosive, and are not affected by tropical or arctic climes. They do not deteriorate by being stocked 10–15 years.

Lubrication Troubles from Uncleansed Castings.

When a new engine or turbine is first set to work, there is certain to be trouble with bearings in perhaps a majority of cases. This is because so many constructors neglect the proper cleansing of castings. Castings are never properly cleaned of sand even externally by the still common methods of steel brushing and coke rubbing, and in steam ports and passages it is hopeless to expect cleanliness from such antiquated methods. 'Sandblasting' with chilled-steel pellets will clean a casting externally, but cannot be relied on for the internal cleansing of ports or oil receptacles. Thus it is that lubrication troubles are so usual when starting up new sets. Some engineers strongly favour the pickling of castings as the most effective way of removing sand. The castings are first roughly cleaned and fettled, and then hosed with weak hydrochloric acid. Where sand is present this spreads the acid by capillary action, and the result of a few hours of acid action is to remove all sand and leave the iron surfaces clean and free also from the hard siliceous scale which is so destructive of turning tools and other tools, especially millers, and is also most injurious to lathe-bed surfaces and other working surfaces of all machine tools. When the acid treatment has done its work, the castings are washed by warm water, and this may be dosed with soda to neutralise any unspent acid.

Note on Lubrication.

Special attention should be given to all internal parts such as box beds, which act as oil receptacles, as well as to steam and exhaust passages. The oil of any circulating system becomes dirty with use. Dirt comes over from the boilers with the steam and finds its way into turbine bearings in spite of all the constructive care to guard against this. The atmospheric dust gets in somewhere, and there may be leakage at oil coolers. There is also the microscopic metallic waste from bearings. All these sources of dirt are quite enough to call for filtration, apart from the gross carelessness which is shown by the presence of foundry sand. Oil may sometimes be at fault if it has been chosen wrongly, but more usually sand, which ought never to have found itself so far from the foundry, is to blame. Organic oils deteriorate with age owing to their property of absorbing oxygen; this causes them to become gummy or resinous, and thus to lose their lubricating quality. Mineral oils, which are not, chemically speaking, oils, do not absorb oxygen, and are free from this deterioration.

NOTE.—The viscosities given in this table were determined by Coleman's Viscosimeter.

SIMPLE TESTS FOR LUBRICATING OIL.

Colour.—A good oil, before use, will appear of a pale yellow colour, and will not separate into layers of different shades, or deposit sediment after being allowed to stand for a few days. It will not rust or corrode in any way any pieces of ordinary polished tool steel suspended in it.

Emulsion.—When mixed with warm water and shaken in a bottle the oil will soon separate entirely from the water and show no soapy emulsion. The test does not apply to marine engine oil nor to black cylinder stock oils which are blended, for obvious reasons, to produce this very emulsion.

Acidity.—Tests with blue litmus paper will show whether any acid is present. The presence of acid is detrimental to machinery of every kind.

Wax Content.—At ordinary temperatures it is a difficult matter to decide whether wax, either in the form of solid paraffin or some other substance, is or is not present. The readiest test is to cool the oil with ice, when the wax will have a tendency to separate out, and so cause the oil to appear cloudy.

All good oils will prove good lubricants if any objectionable content is removed by filtering. Filtered oil is as good as any other oil; and if one oil is found to be a better lubricant than another it will generally be found that the results have depended entirely on local conditions. In more than one instance a warship has managed to get ordinary fuel oil mixed with ordinary machine oil, and has gone on using it as a lubricant for every purpose, and with satisfactory results.

Filtration of Oil.

When oil is properly filtered is can be used indefinitely without losing any of its lubricating qualities.

Recovery of Lubricating Oil.*

Settlement and Filtration Method.

Fig. 1 shows a waste oil filter made by Messrs. A. C. Wells & Co.; these filters consist of three compartments, any of which can be readily removed from the other to facilitate cleaning.

The top chamber receives the dirty oil, which after admission is allowed to settle for about a day, the time varying with the degree of foulness attained by the oil. The top chamber is provided with a floating syphon which when set in operation delivers the settled oil drop by drop into the second compartment, whence it passes by gravity through a special filter pad into the lowest compartment. The descending oil is collected off the underside of the filter pad in the second stage and led into a tube which terminates in a further filter pad. This cleans the oil by upward filtration, the recovered oil falling into the bottom of the third, or lowest, compartment, whence it is drawn off for re-use as required. The whole process of settlement and filtration requires about three days to complete, but by heating the oil with steam coils or electric heaters the capacity of the filter can be practically doubled.

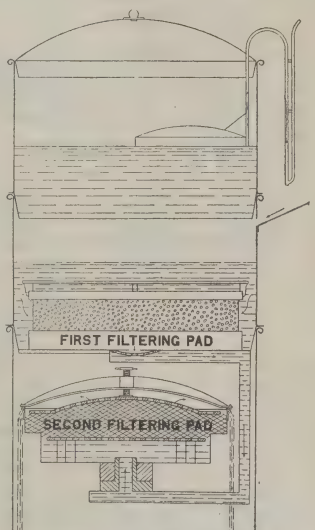

FIG. 1.

Boiling Water Method.

Compound oils can be cleaned by passing them over boiling water.

One of the most satisfactory examples of this system is that installed at the Generating Station of the Chelsea Electricity Supply Company. The waste oil from the engines, excluding that drained from the compressors, is collected into a common tank, whence it is pumped into a larger tank placed at a height of about 8 ft. above floor level. A pipe from this elevated tank is led to a cylindrical open top tank of about 50 gallons capacity which stands on the floor beneath. This latter tank (fig. 2, p. 916) is the one used for the boiling treatment, and is filled with water to a height of 12 ins. or thereabouts. The water is raised to boiling-point by means of a steam coil immersed therein. The dirty oil is then slowly fed into the tank by gravity and the flow is regulated by a valve, so that the mixture of oil and water is maintained at a temperature which causes a yellow froth to appear on the surface. When about 30 gallons of dirty oil have been so introduced the supply is shut off and also the steam heater. Settling then takes place and is allowed to continue for some hours, the treated oil being drawn off through cocks at different levels and put into a filter, leaving a deposit of carbon particles on the top of the water. The filter to which the oil is transferred is divided into an upper and a lower compartment, the treated oil when cooled being drawn off by a floating suction pipe and passed into the lower compartment. This arrangement ensures that oil from the upper surface only of the cooled oil shall be passed into the lower compartment, from whence it is drawn off for re-use. No filtering medium is used, the carbon, etc., which has escaped removal in the boiling tank settling out in the first compartment of the filter.

* Abstract of paper by Alfred J. Wilson, A.M.I.Mech.E., A.M.I.Pet.Tech., read before the Diesel Engine Users Association, 21st Oct., 1920.

Other methods are those in which :—

(1) The oil is allowed to settle either with or without warming. Objections to this method are the length of time and the large number of settling tanks required.
(2) The oil is warmed and then cleaned by chemical means.
(3) The oil is passed through a centrifugal cleaner.

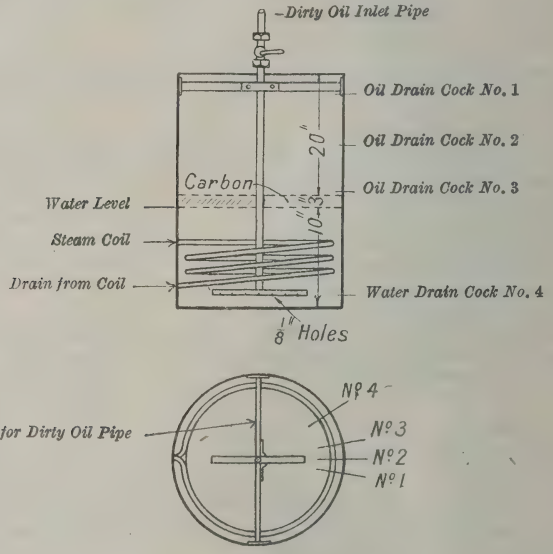

FIG. 2.

LUBRICATORS.

THE V.S.M. AUTOMATIC FORCED LUBRICATION SYSTEM.

In the V.S.M. System of Lubrication (*Messrs. Vickers, Ltd.*) the oil is forced in between the shaft and its bearings at the point of maximum pressure. This is done by means of a pump, which is only about $\frac{3}{8}$-in. diameter, with a stroke of about $\frac{3}{16}$ of an inch. Preferably one such pump is provided for each bearing. The pump works in a closed circuit of oil, and the same oil is used over and over again. *Whenever the pressure per square inch between the shaft and its bearing increases, due to the weight of the shaft or to external stresses, the pump automatically raises the pressure of oil to meet and overcome this resistance, and forces it through to form a positive and unfailing film between the two surfaces exposed to maximum pressure.*

Fig. 3 shows the forced lubrication system applied to a 2½-in. swivel bearing. The pump is surrounded by a reservoir of oil, which has the effect of flooding the inlet openings in the pump body. In this way a suction valve is dispensed with, and the pump plunger is, in effect, its own valve.

The action of the pump is as follows : When the plunger rises to the top of its stroke the inlet openings in the pump body are fully exposed, and oil from the reservoir flows in through these openings, filling the available space in the pump chamber. In making the return stroke the pump plunger gradually passes the inlet openings and finally cuts off the connection between the pump chamber and the external reservoir. The remainder of the downward stroke forces the oil imprisoned in the pump chamber past the non-return delivery valve into the delivery channel, and thence into the bearing on the surface exposed to maximum pressure. This action is repeated with every revolution of the shaft, and in large slow-running shafts the eccentric can be replaced by a cam giving two or more pump strokes per revolution as required.

Each stroke of the pump delivers a definite volume of oil to the bearing, and at the same time displaces an equal volume from the bearing. The displaced oil falls into the chambers provided at each end of the bearing, and flows back, by simple gravity only, into the reservoir surrounding the pump.

In cases where the V.S.M. System of Lubrication has to be applied to bearings and structures already in existence, and where it is impossible to incorporate the V.S.M. apparatus in the design and structure of each bearing, a multiple pump arrangement is adopted consisting of a number of units up to twelve in number. The principle of the arrangement is exactly the same as that shown in fig. 3. To ensure that each bearing gets its proper supply of oil, a separate pump is provided for it, with delivery pipe.

The multiple pump can be driven by a belt or chain, or it can be coupled up to another shaft. The eccentrics operate the pumps exactly as described. The oil flows by gravity from the reservoir past the stop valve through channels to the regulating valves. The oil drops by gravity into the suction side of the pump, and is then forced past the delivery valve on the way to the bearing to be lubricated. Glass tubes are provided for convenience to exclude dust and yet at the same time to enable one to watch the amount of oil passing to each bearing.

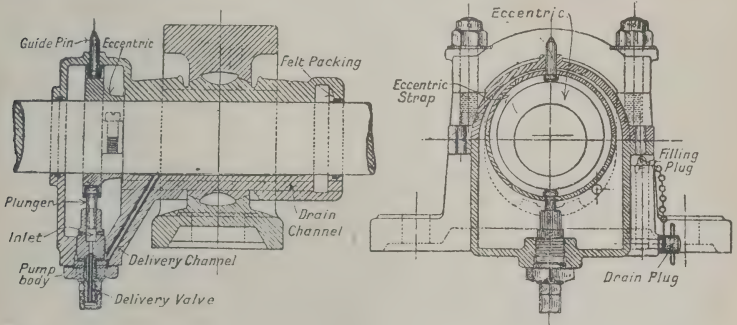

FIG. 3.

In the application of the V.S.M. system to an axle-box for railway rolling-stock the eccentric pump and accessories are substantially the same as those used for ordinary fixed bearings. With fixed bearings, however, the pressure on the bearing itself is usually on the under side, but in railway axle-bearings the pressure is on the top side, and in addition the bearing on the under side is entirely cut away. In consequence it is necessary to provide a short pipe, preferably of copper, to convey the oil from the pressure side of the pump to the top of the bearing at the point of maximum pressure. This arrangement permits the oil pump to be fixed at or near the bottom of the oil reservoir, ensuring an ample supply on the inlet side of the pump. The copper pipe leading from the pressure side of the pump to the top of the bearing is made long with bends, so that any relative movement between the top bearing and the pump may take place in the bends without stressing the unions at both ends of the pipe. Preferably the pump itself is designed as a separate piece from the axle-box for the purpose of manufacture, inspection, and more convenient application to the axle-box.

With a railway axle-bearing having an oil reservoir the great difficulty is to prevent the surplus oil escaping along the axle through the inner end of the axle-box, and so rapidly emptying the reservoir. Another difficulty is to prevent the dust entering through the same space and acting as an abrasive on the axle and its bearings, and causing the rapid wear of both. To overcome these difficulties a special ring has been provided to act as a dust excluder and oil retainer.

(1) For light shafts which carry, say, only pulleys, horse-power = $0{\cdot}013 \times D^3 \times N$.
(2) For shafts carrying gears, horse-power = $0{\cdot}01 \times D^3 \times N$.
(3) For shafts which are heavy, such as main line shafting, horse-power = $0{\cdot}008 \times D^3 \times N$, where, D = Diameter of shaft in ins. N = Number of revolutions per minute.

These formulæ have been figured from an allowable torsional strength of, for (1) 4,170 lbs.; for (2) 3,200 lbs.; for (3) 2,570 lbs.; they can be relied upon as being fairly accurate.

(*W. E. Holloway.*)

Hollow shafts resist torsion better than solid ones of the same area of metal. Calling the outer and inner diameters in inches D and d, then

$$\text{Breaking torsional force, in lbs.} = \frac{(D^4 - d^4) \times \text{Constant}}{\text{Leverage in feet} \times D}.$$

The faster a shaft revolves under the same horse-power, the less is the torsional strain upon it.

Distance between Supports in Ordinary Shafts.

d = diameter of shaft, in inches; l = distance between supports, in feet.

$l = \sqrt[3]{d^2}$, where no power is taken off between the supports.

FRANCIS'S TABLE, WHERE POWER IS TAKEN OFF BETWEEN SUPPORTS.

Diameter of Shaft, in Inches.	Distance between Bearings, in Feet.	
	Wrought-iron Shafts.	Steel Shafts.
2	15·46	15·89
3	17·70	18·19
4	19·48	20·02
5	20·99	21·57
6	22·30	22·92
7	23·48	24·13
8	24·55	25·23
9	25·53	26·24

Where power is taken off by rigger between supports, each case should be separately considered; 7 to 12 feet is usual.

Speed of Shafting.

Shafting for metal-cutting machines . . . 200 revolutions per minute.
" for wood-working . . . . . 250 " "
" for cotton and woollen mills . . . 300 " "

Hollow shafting has been run at 600 revolutions per minute.

DIAMETER OF AXLE, SHAFT, AND CRANK-PIN.

Diameter of Axle.

d = diameter in inches, in the bearing; and the length of the bearing, $1{\cdot}5d$.
W = weight in pounds, acting in the bearing.

Waterwheels.	*Common Machinery in good order.*
$d = \frac{\sqrt{W}}{18}$, for cast iron.	$d = \frac{\sqrt{W}}{24}$, for cast iron.
$d = \frac{\sqrt{W}}{21}$, for wrought iron.	$d = \frac{\sqrt{W}}{28}$, for wrought iron.
$d = \frac{\sqrt{W}}{26}$, for steel.	$d = \frac{\sqrt{W}}{34}$, for steel.

EXAMPLE.—A waterwheel weighs 58,680 lbs., and is supported in two bearings. Required the diameter of the wheel axles. The weight acting in each bearing will be $\frac{58680}{2} = 29{,}340$ lbs., and diameter $d = \frac{\sqrt{29340}}{21} = 8{\cdot}15$ inches of wrought iron.

Diameter of Shaft.

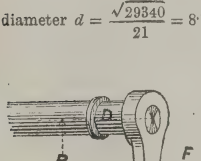

FIG. 1.

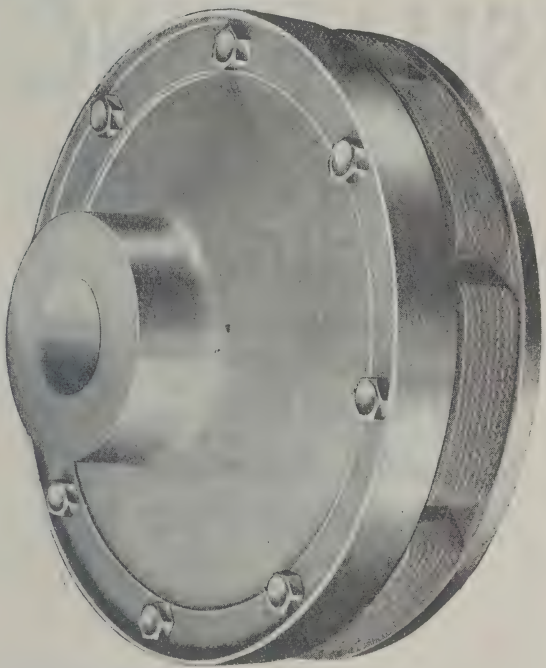
D = diameter of shaft, in inches. R = Radius of crank, in feet.
F = force from the steam piston, in pounds.



$$D = \sqrt[3]{\frac{FR}{80}}, \qquad F = \frac{D^3 \times 80}{R}, \qquad \text{for wrought iron.}$$

$$D = \sqrt[3]{\frac{FR}{120}}, \qquad F = \frac{D^3 \times 120}{R}, \qquad \text{for steel.}$$

EXAMPLE.—The force on the piston in a steam-engine is F=45,600 lbs., applied direct on a crank of R = 3 feet radius. Required the diameter of the shaft, the latter being of wrought iron.

$$\text{Diameter of shaft } D = \sqrt[3]{\frac{45600 \times 3}{80}} = 11{\cdot}96 \text{ inches.}$$

FLEXIBLE SHAFT COUPLINGS

ELECTRO-METALS Z.V. FLEXIBLE COUPLIN

Our Couplings take up eccentricity in shafting; are resilient, well-balanced, and specially . . . designed for heavy service. . . .

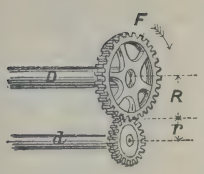

FIG. 2.

$$D = \sqrt[3]{\frac{H}{n} \times 125}, \quad \text{for wrought iron.}$$

$$D = \sqrt[3]{\frac{H}{n} \times 83{\cdot}3}, \quad \text{for steel.}$$

H = the horse-power transmitted. n = the number of revolutions per minute.

$$D : d :: \sqrt[3]{R} : \sqrt[3]{r}, \quad \text{or,} \quad d = D\sqrt[3]{\frac{r}{R}}.$$

EXAMPLE.—A cog-wheel of R = 6·5 feet radius is to gear with a pinion of r = 1·25 feet radius, and to transmit an effect of 231 horses (H) with 42 revolutions per minute (n). Required the diameter of the wheel and pinion shafts. The force F is acting uniformly at the periphery.

$$\text{Diameter of wheel-shaft } D = \sqrt[3]{\frac{231}{42} \times 125} = 8{\cdot}8 \text{ inches.}$$

$$\text{Diameter of pinion-shaft } d = 8{\cdot}8\sqrt[3]{\frac{1{\cdot}25}{6{\cdot}5}} = 5{\cdot}1 \text{ inches.}$$

Diameter of Crank-pin.

$$d = \sqrt{\frac{F}{1200}}, \quad \text{for wrought iron.} \qquad d = \sqrt{\frac{F}{1570}}, \quad \text{for steel.}$$

$$\text{Length of pin} = \frac{3d}{2}.$$

EXAMPLE.—The pressure on pin = 27,000 lbs. Required the diameter and length of pin of wrought iron.

$$d = \sqrt{\frac{27000}{1200}} = 4\tfrac{3}{4} \text{ inches.}$$

$$\text{Length of pin} = 4\tfrac{3}{4} \times \tfrac{3}{2} = 7 \text{ inches.}$$

Board of Trade Rules for the Dimensions of Steamship Shafts.

Main, tunnel, propeller and paddle-shafts should not be less in diameter than that found by the following formulæ. It will be found that first-class makers generally put in larger shafts than those obtained by the formulæ.*

For compound condensing engines with two or more cylinders, when the cranks are not overhung:

$$S = \sqrt[3]{\frac{C \times P \times D^2}{f\left(2 + \frac{D^2}{d^2}\right)}}. \qquad P = \frac{f \times S^3}{C \times D^2\left(2 + \frac{D^2}{d^2}\right)}.$$

Where

S = diameter of shaft, in inches.

d^2 = square of diameter of high-pressure cylinder in inches, or sum of squares of diameters when there are two or more high-pressure cylinders.

D^2 = square of diameter of low-pressure cylinder in inches, or sum of squares of diameters when there are two or more low-pressure cylinders.

P = *absolute* pressure in pounds per square inch; that is, boiler pressure plus 15 lbs.

C = length of crank, in inches. f = constant from following table.

NOTE.—Intermediate-pressure cylinders do not appear in the formulæ.

For ordinary condensing engines with one, two, or more cylinders, when the cranks are not overhung:

$$S = \sqrt[3]{\frac{C \times P \times D^2}{3 \times f}}. \qquad P = \frac{3 \times f \times S^3}{C \times D^2}.$$

Where

S = diameter of shaft, in inches.

D^2 = square of diameter of cylinder in inches, or sum of squares of diameters when there are two or more cylinders.

P = *absolute* pressure in pounds per square inch; that is, boiler pressure plus 15 lbs.

C = length of crank, in inches. f = constant from following table:

* When shafts are proposed to be fitted whose diameters are less than 6 inches, the case should be submitted for consideration.

For two Cranks. Angle between Cranks.	For Crank and Thrust Shafts.	For Tunnel Shafts.	For Propeller Shafts.

When there is only one crank the constants applicable are those in the table opposite 180°.

Lloyd's Rules for the Dimensions of Steamship Shafts.

The diameters of intermediate shafts are to be not less than those given by the following formula:

$$d = (\kappa_1 A + \kappa_2 B + \kappa_3 C + \kappa_4 D + \kappa_5 S)\sqrt[3]{P},$$

in which

d = diameter of shaft, in inches. P = boiler pressure above atmosphere, in lbs. per square inch. S = stroke of piston, in inches. A = diameter of high-pressure cylinder, in inches. B = diameter of first intermediate cylinder, in inches. C = diameter of second intermediate cylinder, in inches. D = diameter of low-pressure cylinder, in inches. $\kappa_1, \kappa_2, \kappa_3, \kappa_4, \kappa_5$ = coefficients according to the following Table:

Description.	κ_1	κ_2	κ_3	κ_4	κ_5
Compound engines with two cranks at right angles . .	·04	0	0	·006	·02
Triple-expansion engines with three cranks at equal angles .	·038	·009	0	·002	·0165
Quadruple-expansion engines with two cranks at right angles	·034	·011	·004	·0014	·016
Quadruple-expansion engines with three cranks . . .	·028	·014	·006	·0017	·015
Quadruple-expansion engines with four cranks . . .	·033	·01	·004	·0013	·0155

The diameter of crank shaft, and of thrust shaft under the collars, to be at least $\frac{2}{10}$ths of that of the intermediate shaft. The diameter of thrust shaft may be tapered off at each end to the same size as that of the intermediate shaft.

For direct coupled and for geared steam turbine engines the diameter of the intermediate shaft in inches $= \sqrt[3]{\frac{70 \times \text{SHP}}{\text{R}}}$, where SHP is the shaft horse power at full power; R is the number of revolutions per minute of the shaft, at full power. The diameter of the thrust shaft under the collars to be at least $\frac{2}{10}$ths of that of the intermediate shaft.

The diameter of the screw shaft to be equal to the diameter of intermediate shaft (found as above) multiplied by $\left(\cdot 63 + \frac{\cdot 03\,\Delta}{d}\right)$, but in no case to be less than $1{\cdot}07d$; where Δ = diameter of propeller, d = diameter of intermediate shaft, both in inches.

This size of screw shaft is intended to apply to shafts fitted with continuous liners the whole length of the stern tube. If no liners are used, or if two separate liners are used, the diameter of the shaft should be $\frac{2}{10}$ths that given above.

The diameter of screw shaft is to be tapered off at the forward end to the size of the crank shaft.

NOTE.—The rules are intended to apply to two-cylinder compound engines, in which the ratio of areas of low and high pressure cylinders does not exceed 4·5 to 1; to triple-expansion engines, in which it does not exceed 9 to 1; to quadruple-expansion engines, in which it does not exceed 12 to 1; and in all cases, as regards the stroke, in which the length of stroke is not less than one-half the diameter or greater than the diameter of the low-pressure cylinder.

Bureau Véritas Rules for the Dimensions of Steamship Shafts.

IRON CRANK SHAFTS FOR SCREW STEAMERS.

When the crank of a screw-engine is not overhung :—
For non-compound condensing engines :

$$d = \sqrt[3]{\frac{nPLD^2}{C}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (A)$$

For double, triple, and quadruple expansion engines :

$$d = \sqrt[3]{\frac{PL(n_1D_1^2 + 0{\cdot}1nD^2)}{C}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (B)$$

For shafts having a single overhung crank the form under the radical sign is to be multiplied by $s + \sqrt{s^2 + 1}$.

For two-cylinder single-crank tandem engines the formula will be :—

$$d = \sqrt[3]{\frac{PL(D_1^2 + 0{\cdot}1D^2)(s + \sqrt{s^2 + 1})}{C}} \quad . \quad . \quad . \quad . \quad . \quad . \quad (C)$$

In these formulæ :
d = diameter of the after-shaft bearing, in inches. n_1 = number of high-pressure cylinders. D_1 = diameter of each high-pressure cylinder, in inches. If there are several high-pressure cylinders, the diameters of which are not the same, $n_1D_1^2$ represents the sum of the squares of their respective diameters. n = number of low-pressure cylinders. D = diameter of each low-pressure cylinder, in inches. If there are several low-pressure cylinders, the diameters of which are not the same, nD^2 represents the sum of the squares of their respective diameters.

NOTE.—For triple or quadruple expansion engines no account is taken of the intermediate cylinders.

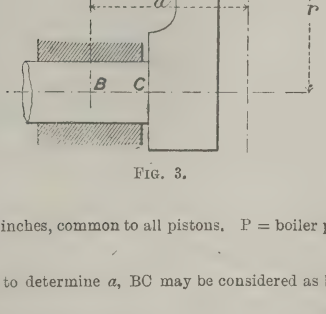

FIG. 3.

L = length of stroke, in inches, common to all pistons. P = boiler pressure above atmosphere, in pounds per square inch.

$s = \frac{a}{r}$ (fig. 3). In order to determine a, BC may be considered as being equal to one-quarter of the length of the bearing.

C = a constant, the values of which are given in the table, p. 926, for certain cases.

If diameter of shaft is above 15 ins. it should be increased by an amount to be determined by the Administration ; for built-up shafts this latter increase will not be required.

For hollow shafts the diameter must be increased by

1	per cent. if the diameter of the hole is 0·4 of the outside diameter.					
2	,,	,,	,,	0·5	,,	,,
5	,,	,,	,,	0·6	,,	,,
10	,,	,,	,,	0·7	,,	,,

If the hole is under 0·4 of the outside diameter, no increase will be required.

PROPELLER, TUNNEL, AND THRUST SHAFTS.

Diameter of propeller shaft is to be found from the formula

$$\delta = d + \left(1{\cdot}7\frac{D}{d} - 15\right)\frac{d}{100},$$

where,
δ = diameter of propeller shaft; D = diameter of propeller; d = diameter of crank shaft calculated from one of formulæ (A), (B), or (C), all in inches.

It is recommended to fit the propeller shaft in such a way that it cannot move endways if for some reason or other it has been uncoupled from the rest of the shafting. Liners fitted on propeller shafts to be tapered off at ends.

For tunnel shafts a reduction of 6 per cent. on the diameter of the crank shaft will be allowed.

The diameter of thrust shaft at the bottom of the collars, both between and immediately beyond these latter, to be equal to that of the crank shaft, and tapered off at each end to the smaller diameter of the body of the shaft. The thrust of the screw propeller must be taken up by an efficient thrust block, so as to prevent any fore-and-aft strain on the crank shaft.

SHAFTS FOR PADDLE-ENGINES.

In side-wheel steamers having double, triple, or quadruple expansion engines, with an intermediate shaft, each end of which carries an overhung crank-pin, fitting loosely into an eye of

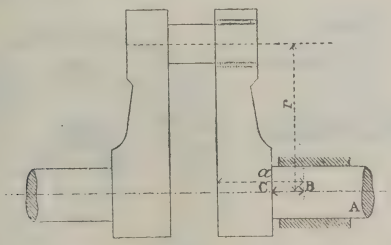

FIG. 4.

the paddle shaft crank, the bearing of the latter (see A of fig. 4) must have its diameter calculated from the formula:

$$d = \sqrt[3]{\frac{PL(n_1D_1^2 + 0{\cdot}1nD^2)\,(s + \sqrt{s^2+1})}{C}},$$

where the letters have the same meaning as before, except that a, for determining $s = \frac{a}{r}$, is to be measured as shown in the annexed figure, B C being equal to one-quarter of the length of the bearing.

For two-cylinder compound receiver engines with two cranks at 90°,
C = 7,100 for coasting vessels, = 5,700 for sea-going vessels.

For triple-expansion engines with three cylinders and three cranks at 120°,
C = 8,150 for coasting vessels, = 6,540 for sea-going vessels.

STEAM TURBINE SHAFTING.

Diameter of tunnel shafts to be determined by the formula

$$d = \sqrt[3]{\frac{61 \times HP}{R}}$$

where,
d = diameter of shafting in inches; HP = power transmitted by the shafting; R = number of revolutions per minute.

Rotor shaft to have a diameter at least 5 per cent. greater than that of tunnel shaft. Diameter of propeller shaft to be determined by the formula

$$d_1 = d + \frac{D}{160}$$

where,
d_1 = diameter of propeller shaft in inches; D = diameter of propeller in inches; d = diameter of tunnel shafting in inches.

Flexible Couplings.

Flexible couplings are now being used in all cases where it is not possible to ensure shafting being exactly in line.

Experiments over a large number of factories and works have shown that the power absorbed by shafting forms quite a large percentage of that generated. This loss is chiefly due to malalignment, and can be saved by introducing suitable flexible couplings; the same remark also applies in the case of two machines whose shafts are coupled together, and apart, of course, from the actual loss of power sustained, trouble and expense is entailed due to the unnecessary stresses in shafting and bearings.

The 'Z.V.' flexible shaft coupling (manufactured by *Messrs. Electro-Metals, Ltd.*, 56 *Kingsway, London*) is designed generally to absorb shocks and stresses, and for taking up malalignment and wear in bearings; it is in extensive use on many classes of drive.

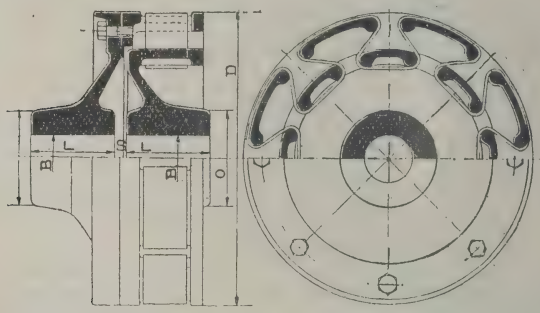

FIG. 5.

The coupling, fig. 5, consists of four parts:

(*a*) The outer disc, which has a suitable boss to take the shaft of the driving member.

(*b*) The belt ring, which is secured to the outer disc.

(*c*) The inner half, which has a suitable boss for taking the shaft of the driven member.

(*d*) A special cotton belt, which passes alternately around the lugs on the inner half and on the belt ring, securing together the two halves of the coupling.

It should be noted that the outer disc can be taken apart without removing the belt. A special advantage of the arrangement is that one shaft is electrically insulated from the other. The coupling, however, is not suitable for reversing drives.

Among the many applications of this coupling may be mentioned the following:

For generators driven by steam, gas, oil, and petrol engines, or motors; for motor-driven centrifugal fans; for direct connected motor-driven shafting in textile and other mills; for motor-driven rolling mills; for direct connection between motors and machine tools, and for connecting one length of shafting with another.

The special grade of belt employed permits of this coupling being used in tropical countries.

SECTION XIX

PART IV

SPRINGS.

HELICAL.

If r = mean radius of spring, in inches, measured from axis to centre of wire; d = diameter, in inches, of wire, if *round* in section; h and b = depth and breadth respectively, in inches, of wire, if *rectangular*; b = breadth and depth, if *square*; n = number of coils of which spring consists; c = coefficient or modulus of transverse elasticity of wire, in lbs. per square inch; W = any load, in lbs., not exceeding the greatest safe load; Δ = corresponding extension or compression, in inches; W_s = greatest safe *steady* load, in lbs.; Δ_s = greatest safe corresponding extension or compression, in inches; f = greatest safe shearing stress per square inch, in lbs.; then

$$\Delta = \frac{Wnr^3}{cd^4}64, \qquad \text{or,} \quad W = \frac{\Delta cd^4}{64nr^3}, \quad \text{for } \textit{round} \text{ wire;}$$

$$\Delta = \frac{Wnr^3}{c\frac{b^3h^3}{b^2+h^2}}6\pi, \qquad \text{or,} \quad W = \frac{\Delta c\frac{b^3h^3}{b^2+h^2}}{6\pi nr^3} \quad \text{for } \textit{rectangular} \text{ wire}$$

$$\Delta = \frac{Wnr^3}{cb^4}12\pi, \qquad \text{or,} \quad W = \frac{\Delta cb^4}{12\pi nr^3}, \quad \text{for } \textit{square} \text{ wire;}$$

$$\Delta_s = \frac{fnr^2}{cd}4\pi, \qquad \text{and,} \quad W_s = \frac{fd^3\pi}{r\,16}, \quad \text{for } \textit{round} \text{ wire}$$

$$\Delta_s = \frac{fnr^2}{c\frac{b\sqrt{b^2+d^2}}{b}}\left(\frac{\pi}{2}\right)^3\frac{3}{\sqrt{2}}, \quad \text{and,} \quad W_s = \frac{f\sqrt{b^2+h^2}}{r}\left(\frac{\pi}{4}\right)^2\frac{1}{\sqrt{2}}, \quad \text{for } \textit{rectangular} \text{ wire.}$$

$$\Delta_s = \frac{fnr^2}{cb}\left(\frac{\pi}{2}\right)^2 3, \qquad \text{and,} \quad W_s = \frac{fb^3}{r}\left(\frac{\pi}{4}\right)^2\frac{1}{2}, \quad \text{for } \textit{square} \text{ wire.}$$

$$\text{Greatest safe sudden load} = \frac{W_s}{2}; \qquad \text{Resilience} = \frac{W_s\Delta_s}{2}$$

$\frac{1}{64} = \cdot0156$; $6\pi = 18\cdot85$; $\frac{1}{6\pi} = \cdot0531$; $12\pi = 37\cdot70$; $\frac{1}{12\pi} = \cdot0265$; $4\pi = 12\cdot57$;

$\frac{\pi}{16} = \cdot196$; $\left(\frac{\pi}{2}\right)^3\frac{3}{\sqrt{2}} = 8\cdot22$; $\left(\frac{\pi}{4}\right)^2\frac{1}{\sqrt{2}} = \cdot436$; $\left(\frac{\pi}{2}\right)^3 3 = 11\cdot63$; $\left(\frac{\pi}{4}\right)^2\frac{1}{2} = \cdot308$.

The value of c for steel in lbs. per square inch may be taken as 16,000,000. The greatest safe value (f) which is certain not to impair the elasticity of the spring by frequent repetition may be taken at 50,000.

From the formula $W_s = \frac{\cdot196fd^3}{r}$, if $f = 50{,}000$, we get,

$$d = \sqrt[3]{\frac{W_s r}{\cdot196f}} = \sqrt[3]{\frac{W_s 2r}{\cdot392f}} = \sqrt[3]{\frac{W_s 2r}{19{,}600}}; \quad \text{Board of Trade rule } d = \sqrt[3]{\frac{W\,2r}{8{,}000}}$$

A spring with its mean diameter small as compared with the size of the bar will allow a higher stress with less set than one of larger mean diameter; size of bar being the same, a spring of small diameter may safely stand higher stress than one of large diameter; springs of too small diameter compared with size of bar are so injured in coiling as to weaken the steel; the ratio of mean diameter of spring to diameter of bar should never be less than 3. For a good grade of steel the following values have been found safe:

Ratio of Mean Diameter to Diameter of Bar.	Safe Torsional Stress.	
3 .	112,000	Bars less than $\frac{3}{4}$ in. in diameter.
8 .	85,000	
3 .	110,000	Bars $\frac{7}{16}$ in. to $\frac{3}{4}$ in. in diameter.
8 .	80,000	

Ratio of Mean Diameter to Diameter of Bar.	Safe Torsional Stress.	
3 .	105,000	Bars $\frac{13}{16}$ in. to $1\frac{1}{4}$ in. in diameter.
8 .	75,000	

For extension springs the value of stress is only two-thirds these values.

(C. H. Benjamin and R. A. French.)

Steel Helical Springs—Round Wire.

(Contributed by R. A. Sturgeon, A.M.Inst.C.E.)

Table of Safe Loads and Scales.

The stresses from which the safe loads are calculated are given for each size of wire. The scale—i.e. the ratio of load to deflection produced—is based on a single coil spring. By dividing the figure given in the table by the number of coils in the spring, the load required to extend or compress the spring 1 in. is obtained. The value of G is assumed to be 12,000,000 lbs. per sq. in.

Multiplying Constants.

1. For compression springs with little variation of load multiply *Safe Loads* by 1·25.

2. For Springs, especially tension springs subjected to considerable variation of load suddenly applied, multiply *Safe Loads* by 0·67.

3. For Square Wire Springs where the Side equals the diameter given in the table—multiply

Safe Load by 1·5
Scale by 1·06

4. For Brass Wire Springs (round) multiply the Scale by 0·42. (Only for *Hard* Brass.)

Note.—In getting out Compression Springs allow for the fact that one coil at each end is idle. These two coils do not affect the Scale, but do affect the closed length.

PHOSPHOR-BRONZE SPRINGS.

The formulæ adapted for phosphor-bronze wire such as is manufactured by the Phosphor-Bronze Smelting Company, of Philadelphia, are as follows :—

$$W=\frac{7{,}000\ d^3}{D-d};\quad F=\frac{8\ P\ (D-d^2)}{6{,}200{,}000\ d^4}$$

When W = P, then

$$F=\frac{7\ (D-d)^2}{775\ d}$$

W = carrying capacity, in lbs. ; d = diameter of wire, in ins. ; D = outside diameter of coil in ins. ; F = deflection in one coil, in ins. ; P = load, in lbs.

These formulæ for springs of all diameters, ranging from d = No. 10 B. & S. gauge to $d=\frac{5}{8}$ in., are accurate within 10 per cent. They apply equally well to tension springs wound closely without initial tension.

(*H. R. Gilson.*)

Clock Type.

(1)

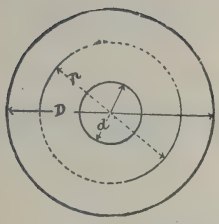

Fig. 1.

Let
d = diameter of inmost coil = spindle + t; D = diameter of outer coil = barrel − t; b = breadth of spring steel; t = thickness of spring steel; L = total length; I = moment of inertia of section; n = number of coils when unwound; n' = number of coils when wound; s = turns from unstrained state; E = coefficient of elasticity; a = total angle of wind; p = diameter of inner coil unwound, or of outer coil wound; M = moment of spring in inch pounds.

For D = 3d the following obtains :—

$tn = \cdot1273\,D$; $\quad d = 0{\cdot}33\,D$;

$t = \dfrac{\cdot0787\,D}{n'-n}$; $\quad n = \dfrac{\cdot1273\,D}{t}$; $\quad n' = \dfrac{\cdot206\,D}{t}$;

$I = \dfrac{bt^3}{12}$; $\quad L = \dfrac{\cdot3491\,D^2}{t}$; $\quad$ or $\quad L = n \times 2{\cdot}7416\,D$; $\quad a = 2\pi s$;

$M = \dfrac{Ebt^3a}{12L}$; $\quad D = \sqrt{\dfrac{\cdot000859\ M\ (n'-n)^4}{b\,s}}$; $\quad p = \sqrt{\frac{1}{2}(D^2+d^2)}$.

d = usually $30t$. For any spiral, $L = \frac{N}{2}(C+C)$, C and C being the circumferences of extreme coils. Maximum practicable, $D = 160t$.

(2)

If l = length of spring; b = breadth of spring; t = thickness of spring: each in inches. E = Young's modulus of elasticity in lbs. per sq. in.; F = safe tensile strength of material in lbs. per sq. in.; N = number of turns spring is capable of taking. R = radius of box containing spring; r = radius of arbor: each in inches. T = maximum torque of spring.

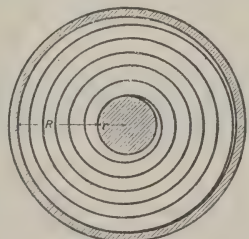

Fig. 2.

$$t = \frac{F}{E} \cdot \frac{(R+r)(R+3r)}{R-r}; \quad b = \frac{6E^2}{F^3} \cdot \frac{T(R-r)^2}{(R+r)^2(R+3r)^2};$$

$$l = \frac{\pi E}{4F} \cdot \frac{(R-r)^2}{R+r}; \quad N = \frac{E}{4F} \cdot \frac{(R-r)^2}{(R+r)^2(R+3r)}.$$

For steel, E = 32,000.000; F = 224,000;
Therefore

$$t = \cdot007\,\frac{(R+r)(R+3r)}{R-r}, \quad b = \cdot547\,\frac{T(R-r)^2}{(R+r)^2(R+3r)^2};$$

$$= 112{\cdot}2\,\frac{(R-r)^2}{R+r}. \quad N = 35{\cdot}7\,\frac{(R-r)^2}{(R+r)^2(R+3r)}.$$

(*J. St. Vincent Pletts: The Engineer, July* 18, 1913.)

Heat Treatment of Springs.

Experiments made by the Automatic and Electric Furnaces, Limited, show that springs heated to 800 degrees and afterwards tempered to 350 degrees give the best results. Overheating is shown to be detrimental; springs which are heated to 900 degrees and quenched, then reheated to 800 degrees and tempered at 350 degrees, show that the bad effects of overheating are not neutralised by reheating to 800 degrees and requenching. These effects can be neutralised by

thoroughly annealing after the first overheating and then by reheating to the correct temperature and quenching.

A spring that has not been overheated, and that has been correctly tempered, can be loaded up to within 5 per cent. of its breaking point without showing any set after the first loading.

Handy Kink for Making Spiral Springs.

Take a piece of fibre about 2 by 6 ins. and bore four or five holes in one end, ranging in size from $\frac{1}{4}$ to $\frac{3}{4}$ in., as in fig. 3. Near the large holes bore several small ones, say $\frac{1}{16}$ in. in diameter. By using nails or pieces of small rod, any size spring can be made, according to the size of the holes.

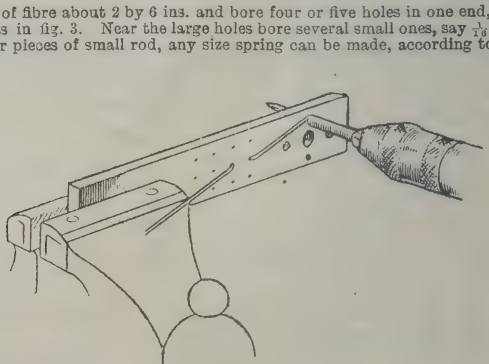

Fig. 3.

Put the block in a vice and thread the spring wire through the holes to give it tension. Take a nail the size of the spring you want to make, cut the head off, and put it into the hole where it fits best. Wrap a few turns of the wire around the nail, and grip the wire and nail in an ordinary brace, as in the figure. Then simply wind the wire around the nail until the desired length of spring is obtained. (*J. W. Fager*, '*Power*.')

Winding a Compression Spring.

Small music wire compression springs can be easily made by the following method. Having selected a mandrel A, fig. 4, the exact diameter of the interior of the desired spring, and wire B, obtain a piece of hard wood C and bore a hole in it in which the mandrel will fit, as shown in the illustration. Within $\frac{1}{32}$ inch from this hole bore another hole, the size of the wire to be used for the spring. Place the mandrel in the chuck of the lathe, slip the piece of wood over the mandrel, and insert the wire in the smaller hole, pushing it through until its end catches in the jaws of the chuck. Now press the piece of wood against the jaws of the chuck and commence winding the spring, first by pulling on the lathe belt, and then by throwing on the power when the coiling operation is well started. During the winding operation, the piece of wood should be pressed firmly against the coils so that the spring will have the appearance of being close wound. When the completed spring is removed from the mandrel, it will elongate or expand, thus forming a compression spring that is the size of the mandrel on which it is wound.

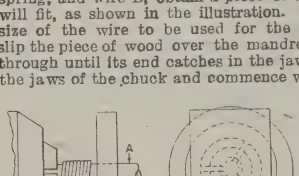

Fig. 4.

If, instead of leading the wire through a small hole as described, a notch is cut in the hole which fits over the mandrel, and the wire fed through this, the inside diameter of the spring will be smaller than the outside diameter of the mandrel. To make the spring a loose fit on the mandrel, the wire should be led through a small hole located at a greater distance from the large hole. If the spring is straightened out by pulling it off from the mandrel, the wire will be badly kinked, but if re-wound by the method described, a good spring will be produced. To remove the strains in the wire spring that result from the winding operation, it should be heated carefully, if made from steel, until it is a uniform blue colour. If the spring is made of phosphor-bronze or brass wire, it should be covered with tallow or beeswax and heated until it smokes. This will remove the strains, so that it will maintain its form. (*J. H. B.*, '*Machinery*.')

METAL CUTTING MACHINES.

LATHES.

With a cutting angle of 80° for cast iron (tool angle 75°) and of 70° for soft steel (the best cutting angles in practice), the horse-power needed at the point of the tool is about 2 h.p. per pound of chips per minute. To this must, of course, be added the power needed to drive the tool light, which, in the case of light cuts, is a large proportion of the whole, and is the main reason why a heavy cut and a slow speed are more economical of power than a light cut at a higher one. Where the chips come off in the same shape and fashion, and the tools are equally sharp, the net horse-power expended in the actual cutting operation is practically the same per pound of metal removed whether a light or a heavy cut is taken. The power to be provided will, of course, depend upon the heaviest cut which the tool is to take. This will generally be heavier in a turret lathe than in a common lathe operating on work of the same diameter.

For the common lathe the heaviest cut is $\frac{1}{40}$th of the height of the centres in depth, and the traverse is $\frac{1}{100}$th of the same height. The area cut is then $\frac{h^2}{6,400}$, where h is the height of the centres. The speed of cutting may be in feet per minute,

$$\text{For soft steel, } v = \frac{10}{\sqrt{a}}. \qquad \text{For cast iron, } v = \frac{3{\cdot}5}{\sqrt[3]{a}}.$$

where v is the cutting speed in feet per minute, and a is the area of cut in square inches.

Keener tools should be used on a material like copper than on steel, and keener on steel than on cast-iron.

In regard to the proper proportioning of the step-pulley and change-gears, the highest speed should be that enabling the tool to give its maximum possible output on the smallest diameter which it is profitable to turn in the lathe, and this may be a diameter of one-eighth the height of centres. The lowest speed should be such that the maximum output is also attained on the maximum diameter which can be swung on the lathe. The geometric ratio between successive speeds should be 1·08 in the case of a 6-inch lathe and 1·24 in the case of a 72-inch lathe. That is to say, if R be the maximum of revolutions per minute provided for and r the smallest, then, in the case of a 6-inch lathe, $R = r\,(1{\cdot}08)^n$, where $n + 1$ is the total number of speed changes.

The highest and lowest Spindle Speeds and their ratio.—These data are fundamental to the design of the fast headstock, and the following figures, rationally deduced, have been confirmed by practice :—

Height of centres . .		6 ins.		12 ins.		18 ins.		36 ins.		60 ins.		
Spindle speeds for carbon steel lathes	Greatest .	300	50	150	50	102	60	50	100	30	180	Ratio
	Least .	6		3		1·7		0·5		0·16		
Spindle speeds for high-heat steel lathes	Greatest .	600	10	300	30	200	50	100	100	60	120	Ratio
	Least .	60		10		4		1		0·5		

The Belt drive.—To enable them to transmit the great powers now required much higher belt speeds have become necessary. Speeds through the air of 2,000 ft. or 3,000 ft. per min. are now used, and unduly wide belts avoided. The efficiency of the belt drive is also improved by using large pulleys running at moderate speeds, rather than small pulleys running at very high rates of revolution.

A simple rational formula for the power required for actual cutting when operating with ordinary high-speed steel on mild steel is :—

$$\text{Cutting HP} = \frac{\text{Force} \times \text{speed of cutting}}{33{,}000}.$$

The force for mild steel is 90 tons per square inch and the standard cutting speed is $\frac{10}{\sqrt{a}}$ where a is the area of cut (cut × traverse) in square inches.

$$\text{Thus C.HP} = \frac{2240 \times 90 \times a}{33{,}000} \times \frac{10}{\sqrt{a}} = 60\sqrt{a}.$$

For standard lathes the test cut in terms of the height of centres is

$$\frac{h}{40}, \text{ and the traverse is } \frac{h}{160}, \text{ or } a = \frac{h^2}{6{,}400}.$$

$$\text{Then C.HP} = 60\sqrt{a} = 60\sqrt{\frac{h^2}{6{,}400}} = 0{\cdot}75\,h.$$

Adding 10 per cent. say for friction in the journals, gears, etc., then gross HP = 0·83 h.

(Nicolson & Smith.)

PLANING MACHINES.

VICKERS' PATENT AUTOMATIC REVERSING DRIVE.

In this system, fig. 1, as applied to a planer, the motor itself reverses and is directly geared to the driving screw or rack-wheel of the machine. There are no driving pulleys to reverse, and the inertia of the driving system is much reduced, permitting quick reversal without the excessive waste of energy shown by a power diagram of the usual type of belt machines. There are no belts to wear. The cost of belts averages 30*l.* to 40*l.* per annum on belt-driven planers of large size. The speed of cutting can be instantly varied between the limits of the slowest cut and of the quick return. Thus, in a planer having slowest cutting speed 15 ft. per min., and (constant) quick return 60 ft. per min., the cut can be varied from 15 ft. to 60 ft. per min. by small intervals, and without altering the quick return speed, by simply turning the handle of the speed controlling switch to the proper position. The speed of the return stroke can be varied in a similar manner. The cutting speed can be instantly suited to the material from the hardest steel to softest steel and wrought iron, thus increasing the general output of the machine. The tool will plane accurately up to a line.

The following is a list of speeds of cutting and return stroke in use with planers which have been converted to this system of drive :—

Size of Planer.	Cutting Speeds.	Return Speeds.	No. of Tools.	Horse-power of Motor.
Feet.	Ft. per Min.	Ft. per Min.		
3 × 3 × 20	30/120	120/30	3	10
4 × 4 × 12	30/120	120/30	3 or 4	15
5 × 5 × 12	30/120	120/30	4	20
6 × 6 × 14	25/100	100/25	4	25
7 × 7 × 18	25/100	100/25	4	30
8 × 8 × 16	20/80	80/20	4	40
9 × 9 × 20	15/60	60/15	4	45
10 × 10 × 20	15/60	60/15	4	45
*12 × 12 × 24	10/40	40/10	Up to 8	50

* Armour-plate planing machines.

VICKERS' PATENT AUTOMATIC REVERSING DRIVE.

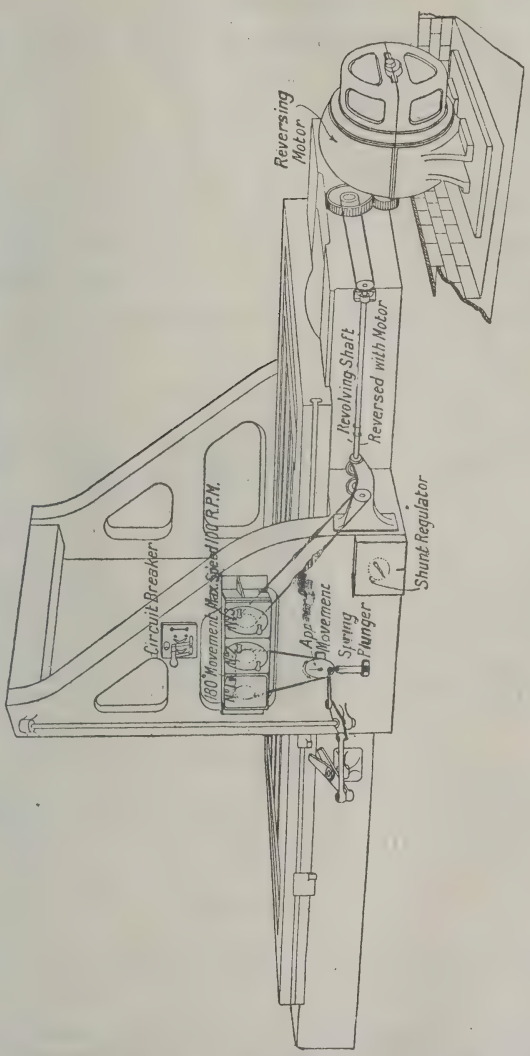

FIG. 1.

Planing Machine Tests.

Material.	Cutting Speed. Feet per Minute.	Depth of Cut.	Feed.	Authority.
		In.	In.	
Steel slabs	25	$\frac{1}{2}$	$\frac{1}{8}$	Armstrong-Whitworth, using A.W. Steel.
Steel horn blocks	35	$\frac{1}{2}$	$\frac{1}{8}$	Armstrong-Whitworth, using A.W. Steel.
Hard cast iron	40	$\frac{1}{4}$	$\frac{1}{8}$	Richard Hornsby & Sons, Ltd.
Cast iron	36	$1\frac{1}{2}$	$\frac{1}{7}$	Armstrong-Whitworth.
Cast iron	55	$\frac{1}{2}$	$\frac{3}{16}$	Armstrong-Whitworth.

Planing Speeds and Feeds.

Material.	Cutting Speed. Ft. per Min.	Feed Ins. per Stroke.	Depth of Cut. Ins.
Roughing Cuts.			
Cast iron	37–48	$\frac{3}{16}$	$\frac{7}{16}$
Cast steel	28–48	$\frac{5}{32}$	$\frac{1}{4}$
Machine steel	28–48	$\frac{5}{32}$	$\frac{1}{4}$
NOTE.—Leave $\frac{1}{32}$ in. of metal for removal by subsequent cuts. When so set, the tools tend to dig in and actually leave about 0·026 in. of surplus stock.			
Straightening Cuts.			
Cast iron	45	$\frac{3}{16}$ to $\frac{1}{4}$	0·018
Cast steel	45	$\frac{1}{8}$	0·018 to 0·021
Machine steel	45	$\frac{1}{8}$	0·018 to 0·021
Finishing Cuts.			
Cast iron	28–35	$\frac{1}{4}$ to $1\frac{1}{2}$	0·003 and 0·001
Cast steel	45	$\frac{1}{32}$	0·004
Machine steel	45	$\frac{1}{32}$	0·004
NOTE.—For cast iron, it is good practice to divide the work up into two operations, taking off 0·003 in. with the first cut and 0·001 in. with the second cut. This prevents a tendency for the tool to dig in at the high spots.			

SPEED TABLE FOR PLANING MACHINES.

(Bateman's Machine Tool Co. Ltd.)

Size of Planer.	Length of Stroke taken.	Time of 10 Cycles.	No. of Feet in 10 Cycles.	Average Speed.	Maximum Speeds. Ft. per min.	
	Ft. Ins.	Min. Secs.		Ft. per Min.	Cut.	Re-turn.
24 ins. by 24 ins. by 6 ft.	6 3½	1 8	126	111	80	225
30 ins. by 30 ins. by 8 ft.	8 0	4 20	160	37	22	218
(With three-speed gear-box)	8 0	2 21	160	68	45	218

(With three-speed gear-box)	20 3	6 14	405	65	42	163
	20 3	4 46	405	85	61	163
42 ins. by 42 ins. by 20 ft.	22 6	6 39	450	68	45	145
42 ins. by 42 ins. by 14 ft.	14 0	3 56	280	71	50	155
42 ins. by 42 ins. by 12 ft.	11 0	2 36	220	84	58	175
48 ins. by 48 ins. by 8 ft.	8 0	2 4	160	77	52	160
60 ins. by 60 ins. by 12 ft.	12 0	6 0	240	40	25	150
(With three-speed gear-box)	12 0	3 50	240	62½	42	150
	12 0	2 50	240	85	60	150
72 ins. by 72 ins. by 16 ft.	16 0	7 40	320	41	25	110
(With three-speed gear-box)	16 0	5 40	320	56	39	110
	16 0	4 50	320	66	50	110

For taking the roughing and straightening cuts, it is usually found that high-speed steel is the most satisfactory material, owing to its greater productive capacity ; but where considerable accuracy and perfection of finish is required in performing the final planing operations, far more satisfactory results will usually be obtained by making the cutting tools of carbon steel, because this material can be ground to a keener edge, and experience has shown that the tools retain this edge longer and are thus able to produce a smoother and more accurate finish on the work.

MILLING MACHINES.*

One of the chief points is to make the cutters of such shape that all the fitting surfaces and cutting edges can be easily and accurately ground. In fig. 2 an ordinary grooving cutter is shown so designed. It will be noticed that the hole is chambered out so that the cutter fits the spindle at the two narrow surfaces, A and A′, only. These surfaces can be more easily ground to standard size than could a bearing the full width of the cutter. After the hole has been accurately finished it is an easy matter to mount the cutter on a mandrel and grind the surfaces BB and B′B′, and also the cutting edges, CC, C′C′, and DD all at the same setting, as indicated in fig. 2. Nothing now remains to be done but to back off the teeth in the way indicated in figs. 3 and 4. Such a cutter, when mounted on a true spindle, provided with a solid collar, against which the cutter is held, is self-setting and accurate.

In determining the correct angle for the face of the teeth, the diameter and shape of the cutter should be taken into account. For small-sized cutters it will, in order to obtain a strong shape, generally be found best to make the faces truly radial, as shown in figs. 2, 3, and 4. This also is more convenient when the cutter is to have teeth both on the sides and periphery. Cutters with the teeth so formed have worked upon both wrought and cast iron perfectly well, and at the same time they are not so liable to seize hold and bite into the work as cutters which have the faces of their teeth undercut. The pitch of the teeth is, again, partly determined by the diameter and class of cutter. In those cutters which are cut at the sides, the pitch at the circumference has often to be made wider than is advisable, in order to give clearance room for the emery wheel

* Abstract of a paper read before the Manchester Association of Engineers.

when grinding the converging side teeth (see fig. 4). A pitch of from $\frac{5}{16}$ inch to $\frac{3}{8}$ inch will usually be found to give good results. In all except very narrow cutters it is advisable to cut the teeth on the periphery spirally. This ensures a smoother action of the machine and produces better work. In deciding whether to make the cutters right- or left-hand spirals, attention should be paid to the direction in which they are to revolve. For example, in a vertical machine whose spindle revolves to the right hand, as in an ordinary drilling machine, the cutters should be cut

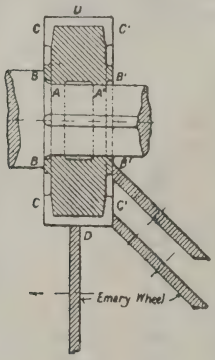

FIG. 2.

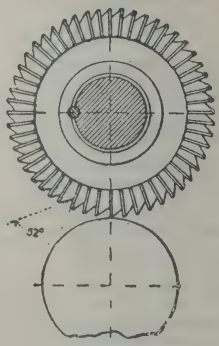

FIG. 3.

with a left-hand spiral. This has the effect of forcing the work down on to the table and the spindle up against its end bearings, as the cutter and the work act as a screw and a nut. In cutters of small size high-class tool steel is most suitable, although great care is required in heating it gradually and evenly. The bottom of the spaces between the teeth should be slightly rounded, and the keyways made semicircular, in order to avoid starting-places for fracture.

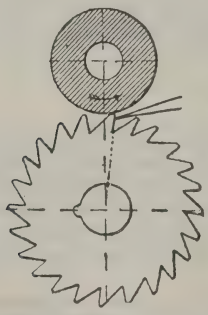

FIG. 4.

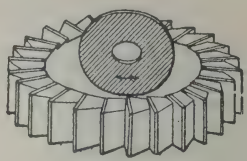

FIG. 5.

For cutters of larger sizes and strong sections Howell's case-hardening steel may be used with great advantage.

Too great stress cannot be laid upon the necessity of keeping milling cutters sharp, and both machines and cutters in such a condition that the cutters shall run true. In grinding milling cutters it is essential that the spindle and emery wheel of the grinding machine should run true and be accurately balanced, as, owing to the high speeds at which they are run, it is clear that any inaccuracy in these respects is highly detrimental. In order to prevent the emery wheel from

glazing, it is necessary to keep it perfectly free from oil or perspiration, and care should be taken not unduly to force the emery wheel against the work, as excessive pressure rapidly generates heat, which not only softens and glazes the emery wheel, but also draws the temper of the thin edges of the cutter, often without showing any discoloration on the edge just ground. For general cutter grinding the emery wheels should be fairly coarse and free-cutting, otherwise they are apt to soften the cutter, which may be known by a fine blue burr, to be seen on the faces of the teeth, the metal along this line being softened. For ordinary-sized cutters an emery wheel 2½ inches in diameter by $\frac{5}{16}$ inch or ¼ inch wide will be found most suitable, the speed of which may vary from 3,000 to 4,500 revolutions per minute, but either too fast or too slow a speed will cause the wheel to burn and soften the cutter. The finishing cut should be very small in amount, especially in cutters of large diameter, otherwise the wear in the diameter of the emery wheel will materially affect the height of the cutter teeth, those last ground being the highest.

For general work, in which ordinary cylindrical cutters can be used, cutters of small or medium size, say up to 3½ inches in diameter, will be found to possess important advantages.

The plain cylindrical cutter is the cheapest and most effective wherever it can be used.

Speed of Milling Cutters.

Table I. shows examples taken from everyday practice, working on wrought-iron forgings.

TABLE I.

Diameter of Cutter.	Depth of Cut.	Width of Cut.	Revolutions of Cutter per Minute.	Cutting Speed in Feet per Minute.	Feed in Inches per Minute.

(*Paper read before the Manchester Association of Engineers*, 1912.)

BROACHING.

Recently the finishing of holes, oil gutters, keyways, etc., by broaching has received considerable attention. Any class of material appears to lend itself to this process provided the broach is of suitable design. Broaches under $1\frac{1}{2}$ ins. diameter are frequently made of high-speed steel containing from 14 per cent. to 18 per cent. tungsten. Such steel, however, is hard throughout and likely to fail under shock. For this reason, some firms make their broaches entirely of vanadium steel, which contains neither tungsten nor chromium. This steel is hardened at 750° C. and quenched in oil and tempered at 420° C. For general work a mild steel containing about 0·15 per cent. carbon, carburised at 900° C., reheated to 800° C. and dipped in water has given very satisfactory results. The reheating before quenching gives a tough core. For broaching hard

steel, a mild steel containing from 2 per cent. to 3 per cent. nickel and about 0·14 per cent. carbon, carefully case-hardened, reheated to 770° C. and quenched in whale oil, has proved suitable. In making a broach, choose a bar with at least $\frac{1}{4}$ in. excess in diameter of the finished broach, so as to avoid small surface cracks and skin stresses. Broaches above 2 ins. diameter are frequently built up, in which case the teeth are formed on hardened steel rings, and these are securely mounted on a mild steel core. The teeth of the broach should be periodically examined when in use. Should any of these be chipped or dulled, these must have the cutting edge restored. Should a tooth break it must be ground down and the cut distributed amongst the next four teeth or so.

In the case of white metal an accurate hole and fair finish may be obtained with a broach having fine pitched teeth (say, from $\frac{3}{8}$ in. to 1 in. in broaches from $1\frac{1}{2}$ ins. to 6 ins. diameter), and each cutting tooth increasing by 0·0005 in. The cutting teeth are preceded by a plain part (to act as a pilot) about 2 in. long and 0·002 in. below the diameter of the first cutting tooth and diameter of the hole. From 6 to 12 teeth at the end of the broach are parallel and about 0·002 in. larger than the finished hole, to allow for creep. This dimension will vary with the springiness of the member. The teeth should have a parallel land of 0·02 in. and a top-take of about 10°.

Design of Broach.

The broach may be secured to the cross-head of the machine by means of a screw or a flat key, or a buttress-thread and pad, a plain cylindrical stem with cotter. An example of the latter is shown in fig. 7. This method is extensively used, on account of the ease with which the pin can be withdrawn and the security it affords, in that the pin is sheared before any damage is done to the broach or machine.

All broaches should be provided with a pilot. The pilot is made a sliding fit in the hole or slot, and leads the cutting edges centrally to their work. It is a very important factor, as it not only helps to produce accurate work, but prevents damage to the broach. In the case of very long broaches, pilots or steadies are provided at intervals along the broach itself, as shown at A, fig. 9. It is advisable that the broach should have four or five teeth at the end for sizing only. These may be of a smaller pitch than the normal, as the cut removed per tooth is exceedingly fine. C, Fig. 9, shows a square broach with progressive increasing cut per tooth which in this design is permissible.

Pitch of Teeth.

The pitch of the teeth is regulated by the number of teeth engaged, the cut taken per tooth, the material operated upon, and the material of which the broach is made. It is clear that the cutting force should not exceed the tensile strength of the broach or strength of the teeth. In the case of broaching, a circular, square or hexagonal hole in mild steel, it is usual to allow of three teeth being in action, each tooth taking $\frac{3}{1000}$ in. cut, that is, 9 teeth thousandths. This is suitable, say, for a broach 1 in. dia., but for a broach $\frac{1}{2}$ in. dia. only 5 teeth thousandths should be allowed, whilst for a 2 in. broach 18 teeth thousandths can be allowed, and a proportionately larger amount as the diameter of the broach increases. With softer material more teeth can, of course, be engaged. It is desirable that the teeth should have a top rake of about 10°, a land of about $\frac{1}{32}$ in., and a side clearance of about 3°, as shown in fig. 8. Proportions of teeth in common use are shown at D, fig. 9.

It is difficult to obtain uniformity of cutting per tooth on the first trial, and the broach may be pulled through a sample piece, the amount removed per tooth being noted, and the teeth honed down where necessary. On rectangular and circular work the teeth are sometimes spiral as shown at B in fig. 9. This design has the advantage of giving a side rake to the cutting edges, and it is claimed that it tends to neutralise any lateral thrust. Occasionally the teeth are staggered, and where the material to be cut is very hard the teeth may be fluted or nicked. An example of the latter is shown in fig. 8, where the alternate teeth are arranged to remove the corner and body of the groove. This arrangement breaks up the chip and materially reduces the stress on the broach.

In fig. 7 is shown the design of a broach adopted for cutting single keyway in a member, and the pilot which is fitted to the machine to guide the broach. Where more than one key is required, arrangements are made to turn the member round, but the spacing obtained under such conditions is rarely accurate, and a better method is to provide for a double spline broach as shown in fig. 8. It is always desirable, where there is more than one gutter, to have a broach with the necessary number of splines.

Speed of Cutting.

The speed of cutting varies with the material operated upon, and for soft brass may be as high as 20 ft. per minute, and for medium hard steel about 5 ft. per minute. The cutting speed is relatively of little importance, and it is generally advisable to adopt about half the above speeds.

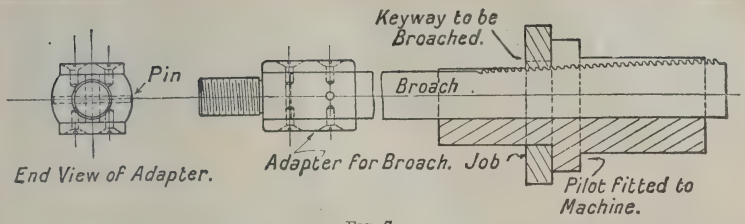

FIG. 7.

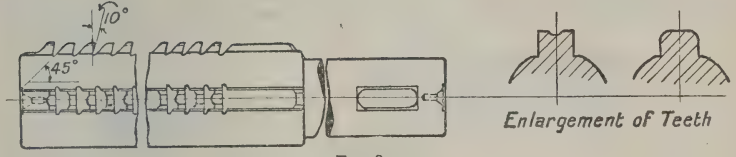

FIG. 8.

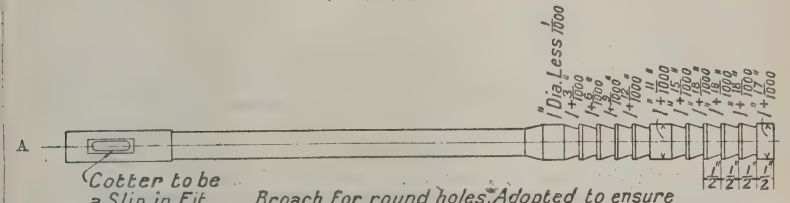

FIG. 9.—Types of Broaches.

Lubrication.

When a highly-polished finish is required on ductile materials it is desirable to use a cutting compound, and on such materials one pint of oil mixed with 4 ozs. of flowers of sulphur has given good results. The J. N. Lapointe Co. recommend the following mixture when broaching mild steel :—

Mineral lard oil, 3 gallons ; water, 50 gallons ; and soda ash, 2½ lbs. The whole of the lard oil and soda ash should be mixed with 10 gallons of water and the remaining proportion of water added before putting into use.

For heavy duty use castor oil.

DRILLS AND DRILLING.

Cutting Edges of Drills.

The cutting edges of drills are formed by grinding the end facets at an angle as shown by A, C, B, fig. 10, and this angle varies from 5° for drilling hard metal, such as steel, to 20° for

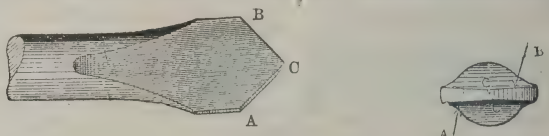

Fig. 10.

soft metal, such as brass or copper. The angle of one cutting edge to the other varies from 45° for steel to about 35° or 40° for soft metals.

Drills for work of ordinary hardness are tempered to an orange purple ; but if the metal to be cut is very hard a straw colour is preferable, or the drill may be left as hard as it leaves the water ; that is to say, hardened, but not tempered. In these cases great care must be exercised and the speed of the drill reduced.

Twist Drills.

A twist drill possesses three cutting edges, A, B, and C, as shown in fig. 11.

The point A, being the least effective, since it cannot be made anything like as keen as the other two, B and C, is a hindrance to clean and rapid cutting and is one of the most important factors to be considered when arriving at the amount of feed progression per inch of travel.

In order to obtain the greatest possible duty from a twist drill, it is imperative that it should be

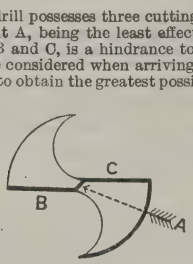

Fig. 11.

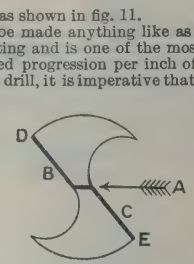

Fig. 12.

ground perfectly true, so that the point of the drill shall be central and in line with the axis on which it revolves. The cutting edges must be of equal length and at the same angle to the axis of the drill. If the point of the drill is not central to the axis, the two cutting edges are not at the same angle, the result being that all the duty falls on one cutting edge, and the hole made will still be larger in diameter than the drill, there being a tendency for the cutting edge B to push, or crowd, the drill over to the opposite side of the hole.

From the foregoing it will be obvious that the more correctly a drill is ground, the longer it will last without re-grinding : the greater its amount of feed may be to take an equal depth of cut, and the nearer the diameter of the hole bored will be to that of the drill.

Another important point when the maximum duty is expected from a twist drill is the relationship between the speed and feed, which varies more or less with different materials and with different grades of hardness of like materials.

When a drill has been in operation for a short time it should be withdrawn from the machine and examined as to its cutting edges, fig. 12. Should the cutting edges B C show more wear towards their extreme diameters D E, this would show the speed is too great as compared with the feed.

The grooves of a twist drill make either a constant angle with the axis or an angle that increases gradually from point to shank. The latter form is supposed to facilitate the escape of the cuttings, though opinions differ, but it has the serious effect of rendering the cutting angle more obtuse as the drill becomes ground back. When the angle is constant it ranges from 24° to 32° with the axis, measured at the periphery, 26° being an average. In the increase-twist drills it ranges roughly between 30° and 25°, the angle lessening by that amount from point to shank. The thickness of the web is increased from point to shank to enable it to resist torsional stresses. The diminished area for the escape of chips consequent on this thickening is counteracted by increasing the twist.

'Firth's Speedicut' High-speed Twist Drills.

The chart (fig. 13) indicates speeds and feeds suitable for drilling mild steel; for cast iron use the same feed per minute but decrease the speed 20 per cent. Both speeds and feeds may be modified to suit variation of material.

The feeds and speeds given on the chart are approximate, and represent ordinary working speeds for average depths of holes.

The chart shows that a 1-in. drill should run under the following conditions.

Mild Steel.	*Cast Iron.*
Speed, 280 revs. per min.	Speed, 224 revs. per min.
Feed, 4¼ ins. per min.	Feed, 4⅛ ins. per min.
Feed per rev., ·0175.	Feed per rev., ·022.

If the material is thin, as in the case of boiler plate, both feed and speed can be increased. If the material is hard, decrease both the feed and speed. Always run with lubricant if possible except in the case of cast iron. If no lubricant is used, decrease both feed and speed about 25 per cent. When possible, always keep the feed per rev. the same as given on the chart for the

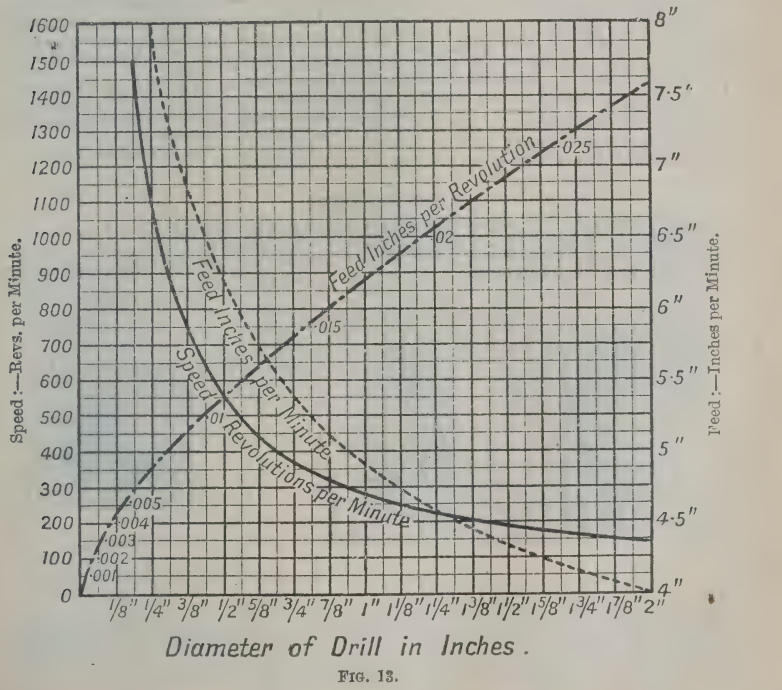

Fig. 13.

two different classes of material, i.e. steel and cast iron. Never decrease the feed below a minimum of, say, 3 ins. per min. for a 1-in. drill, the others in like proportion.

(*Thos. Firth & Sons, Ltd., Sheffield.*)

$\frac{11}{16}$	139	111	278	$2\frac{1}{4}$	42	34	84
$\frac{3}{4}$	128	102	256	$2\frac{1}{2}$	38	30	76
$\frac{13}{16}$	118	93	236	$2\frac{3}{4}$	35	27	70
$\frac{7}{8}$	109	87	218	3	31	25	62
$\frac{15}{16}$	102	81	204				

Feed revolutions for the above speeds, on wrought iron and steel: up to and including $\frac{1}{4}$ in. diameter, $\frac{1}{1\frac{1}{0}}$ in.; from $\frac{1}{4}$ in. up to $\frac{7}{16}$ in. inclusive, $\frac{1}{1\frac{1}{0}}$ in.; from $\frac{7}{16}$ in. up to $\frac{5}{8}$ in. inclusive, $\frac{1}{1\frac{1}{0}}$ in.; from $\frac{5}{8}$ in. up to 1 in. inclusive, $\frac{1}{8\frac{1}{0}}$ in.; from 1 in. up to $1\frac{1}{2}$ in. inclusive, $\frac{1}{8\frac{1}{0}}$ in.; from $1\frac{1}{2}$ in. upwards, $\frac{1}{7\frac{1}{0}}$ in. For cast iron these feeds may be increased 20 per cent.

For small holes in brass the feed should be from 0·0015 in. to 0·003 in. per revolution; $\frac{1}{8}$ in. to $\frac{1}{4}$ in. diameter, 0·003 in. to 0·006 in. per revolution; $\frac{1}{4}$ in. to $\frac{1}{2}$ in. diameter and upwards 0·006 in. to 0·020 in. per revolution. When drilling mild steel the feed should be approximately one-third the above, and harder metals slower in proportion.

Should the drill be running too fast the outer edge of the lip becomes quickly dulled; should the central stem become dull, or the lips chip, the feed is too great.

GRINDING DRILLS.

When grinding the drill points, the following rules should be observed:—

I. Both cutting lips, fig. 14, should be inclined at the same angle with the axis of the drill, and must be of equal length. The point angle of 59° has been universally adopted as best suited for average conditions.

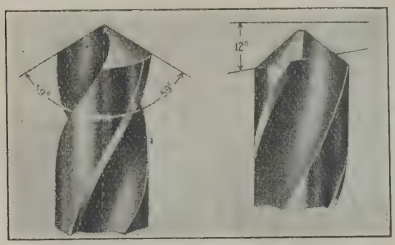

FIG. 14. FIG. 15.

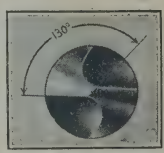

FIG. 16.

II. The drill point must have the proper clearance or contour of surface back of the cutting edges, and this clearance must be identical on both sides. Approximately a 12° clearance angle, fig. 15, combined with the centre angle of 130°, which will give a constantly increasing clearance toward the centre, fig. 16, has proved best for average conditions.

Some of the undesirable conditions resulting from drill points improperly ground are as follows:—

(1) If both lips are not ground at the same angle with the axis, fig. 17, one lip will fail to counteract the tendency of the other to spring away from the cut; consequently, one lip will do more work than the other, which will result in its becoming dull more rapidly than if both lips were cutting equally, and it will be subjected to an abnormal torsional strain.

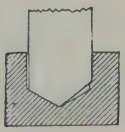

FIG. 17.

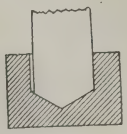

FIG. 18.

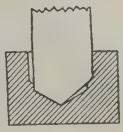

FIG. 19.

(2) When the cutting lips of a drill have the same point angle but are of different lengths, fig. 18, the point of the drill will be off centre, or eccentric. As a result, the hole will be oversize to an extent equal to double the amount of this eccentricity.

(3) If the drill point is ground both with lips at different angles and of different lengths, fig. 19, there will be a combination of the undesirable results described in the two preceding paragraphs.

4. Fig. 20 shows a side and end view of a drill with the proper angle of point (59°) and the proper angle of clearance at the periphery (12°), but with insufficient clearance at the point or centre.

5. Fig 21 shows a drill with insufficient clearance both at the periphery and at the centre. The line ABC is at an angle of 12°, but there is no clearance immediately back of the cutting edges (BC), and the excess of clearance at the heel (AB) is of no benefit.

6. Fig. 22 shows what is liable to happen to a drill ground with insufficient clearance, or as described in paragraphs Nos. 1 to 5, especially if an attempt is made to obtain maximum production.

(7) Fig. 23 shows a drill with a clearance angle of about 12°, but it does not have the proper contour back of the cutting edges. This manner of grinding leaves the cutting edges thin and weak, causing them to crumble away under heavy feeds.

FIG. 21. FIG. 22. FIG. 23.

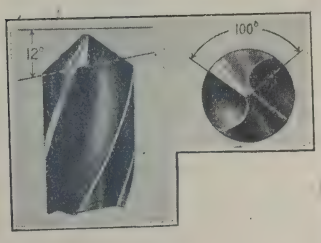

FIG. 20.

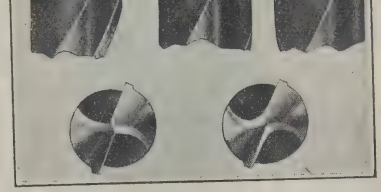

FIG. 24. FIG. 25.

Most twist drills are made with a gradual increase in the thickness of the web or centre of the drill toward the shank. As the drill becomes shorter and the web thicker, greater force is required to drive it. To overcome this, it is good practice to thin the web by grinding away the excess thickness, reducing it to its original dimensions. This grinding must not extend too far up the flute of the drill, and care must be exercised that the cutting lips are not injured

and the same amount is ground out of each groove. Fig. 24 shows a drill with the web properly thinned. In fig. 25 the grinding is excessive, leaving the web entirely too thin and liable to crumble. When this happens a split drill is practically inevitable.

Paragraphs 1 to 5 and the preceding paragraph show the cause of drills splitting up the centre, and no manufacturer should be called upon to replace a split drill unless a flaw is evident in the steel.

Twist drills are made with a slight taper from point to shank, so that the largest diameter is always across the corners of the cutting lips. This prevents the drills from binding in the work when they are sharp. If the outer corners are allowed to become badly worn, the drills will bind and cannot perform satisfactorily. Whenever the outer corners of the cutting lips show wear, the drills should be reground and every particle of worn surface removed, or the drill will continue to bind and very quickly be damaged beyond repair.

In grinding high-speed drills care should be taken not to overheat them, and when heated they should never be plunged into cold water. Doing so is likely to cause small surface cracks, which reduce the efficiency of the drill and may result in serious damage to it. Forcing the grinding on a wet grinder may also bring about the same condition.

It is hardly possible to do grinding as accurately by hand as by using a good twist-drill grinding machine.

Broken or damaged tangs of drills are generally the result of an imperfect fit of the drill shank in its socket, which may be caused by a worn-out socket, dirt or chips accumulating in the socket, or bruises on the shank of the drill.

In any case, the driving power of the taper is reduced or destroyed, resulting in an abnormal strain being put upon the tang.

A drill of either carbon or high-speed steel that can be filed is not necessarily too soft for service; in fact, if drills were tempered so that a good file would make no impression, they would be entirely too hard for general use. If there is any doubt regarding the temper, try the drills in actual service.

Assuming the drill is properly ground, when the corners of the cutting lips wear away rapidly, it is an indication that the speed is too great. If the cutting edges roughen or break out in minute particles it indicates that the feed is too great.

It is seldom that very small drills can be run at more than a fraction of the speed necessary to obtain the best results, and excessive breakage is inevitable. They should be run true and the cutting edges kept sharp; a fine-grade emery stone is best suited for this latter purpose.

(*Iron Age*).

Notes on Drilling.

The power for a given diameter of drill and feed is proportional to the cutting speed.

The horse-power is proportional to the torque, and for a given drill and speed does not increase as fast as the feed.

Since the torque is practically proportional to the diameter of the drill squared, the horse-power, for a given feed and cutting speed, is directly proportional to the diameter of the drill.

The horse-power per cubic inch of metal removed is inversely proportional to the feed and independent of the drill and cutting speed.

The work required to drill a given hole, when one drill is used, is greater than that required to drill the same hole in two operations with drills of different diameters. The greater the difference in the drill diameters, the greater the saving in work; speed and feed remaining the same throughout. This is due to the fact that the mean cutting angle of the single drill is greater than the average angle in use for the two drills and that the stress is proportional to the angle.

With twist drills of the usual proportions, the cutting angle is not sufficiently keen to drag the drill into the work when enlarging a hole in cast iron or steel.

The horse-power when operating on soft cast iron or medium steel varies as $t^{0\cdot7}$ (t = feed per rev.) for a given drill and speed.

The horse-power for a given feed and speed does not increase as fast as the diameter but varies as $d^{1\cdot8}$.

The torque and horse-power when drilling medium steel is about 2·1 times that required to drill soft cast iron with the same drill speed and feed.

The end thrust when operating on cast iron or steel does not increase in proportion to the feed for a given diameter of drill or in proportion to the diameter for a given feed.

While the chisel point scarcely affects the torque it is accountable for about 20 per cent. of the end thrust.

Lubricated trials on steel when compared with the dry tests show a diminution in the torque and horse-power, varying from 28 per cent. with the $\frac{1}{100}$ feed to 8 per cent. with the $\frac{1}{8}$ feed. This may be due to the lubricant washing away the small metal chips which tend to jam between the walls of the hole and the drill, and to the preserved cutting edge. The diminished frictional resistance of the shaving across the lip together with above reduces the end thrust by about 25 per cent. for all feeds.

As the result of a series of experiments on twist drills, recently undertaken at the engineering experiment station of the Illinois University, the following lubricants are recommended:—For tool steel—lard oil, machine oil, turpentine, soda-water, kerosene; for soft steel—lard oil, machine oil, soda-water; for cast iron—dry or compressed air; for brass—dry or paraffin oil; for aluminium—kerosene, soda-water, and aqualine and soda-water.

The drill most commonly adopted in practice has an included angle, at the point, of 120 degrees. If this angle is increased the torque diminishes but the end thrust increases, while if this angle is decreased the reverse is the result. So far as economy in power is concerned the torque is the factor to consider, as the feeding horse-power is only about 1 per cent. of the whole in small drills and very much less for the larger sizes. From this point of view the drill with the larger point angle is to be preferred. The accompanying increased end thrust, however, strains the machine parts in proportion. When the point of the drill breaks through the metal at the bottom of the hole, a considerable portion of the end load is removed. The strain due to that load is released, thereby causing the drill to advance more than its rated feed and possibly break the drill. The drill with the greater included angle will be most likely to give trouble in this direction, both on account of the increased strain and torque and conversely.

By decreasing the spiral of the drill a keener cutting angle with a decreased end thrust and torque can be obtained without altering the point angle above the accepted standard, 120 degrees. This, however, would in turn affect the durability of the drill.

With a small included point angle there is little metal to support the cutting edge at the chisel point, and trouble due to blunting of this part is to be expected.

The endurance of a drill may be increased by from 300 per cent. to 1,000 per cent. by rounding the sharp corners at the periphery.

In estimating the time required to drill a hole of given depth, the length of the drill point must be taken into account. The length of the point for different included point angles is:

$$90^\circ = 0\cdot5d; \quad 120^\circ = 0\cdot29d; \quad 150^\circ = 0\cdot134d.$$

(*See also* '*Smith & Poliakoff: Proc. Inst. of Mech. Engrs.* 1909.')

True drilling is usually dependent upon good centering, and it may be advisable to draw attention to the well-known but often ignored rule, namely, that the centering tool must have a lesser cutting angle than the drill point, otherwise the drill will strike on the point, wobble, start out of centre, and sometimes break.

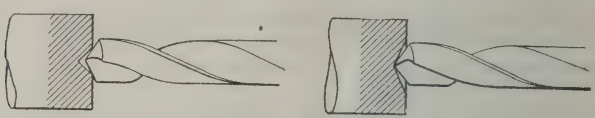

FIG. 27.

Good centering. Bad centering.

Fig. 27 shows good centering at *A* and bad at *B*. As a general rule the centering drill should have an included angle of 100 degrees against the standard angle for the drill point of 119 degrees.

(*Machinery.*)

SMALL DRILL PROTECTOR.

The function of this protector (*Messrs. Brown Brothers, Ltd., Great Eastern Street, E.C.* 2) is to stiffen the shank of the drill, leaving exposed a length of the drill sufficient only for the depth

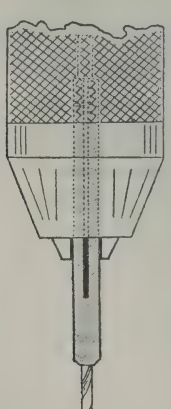

FIG. 28.

of the hole to be drilled. The protector, fig. 28, consists of a length of hard brass, drilled from one end to the other, and with about three-quarters of its length slotted on one side, the internal diameter being equal to the diameter of the drill to which it is to be applied. To use the protector, the drill is inserted therein with the cutting point projecting from the chamfered end, the exposed length being equal to the required depth of the hole to be drilled. The split end of the protector is inserted into the drill chuck so that it is secured for about half an inch of its length, the chuck then being tightened up in the usual manner. If it is required to drill a hole of greater depth than

usual all that is necessary is to release the chuck and slide the protector farther up the drill for the extra length required and then tighten up the chuck again.

The protectors are supplied suitable for short or long length drills in sizes varying from $\frac{1}{32}$ up to $\frac{1}{2}$ in., from 20 to 66 wire gauge sizes and from 1 to 2 mm.

DRILLING MACHINES.

Patent Ball-Bearing Drilling Machine.

In these machines (fig. 29) a high efficiency results from the fact that all running bearings (including the spindle bearings) are annular ball bearings, which never require adjustment. The fact that the spindles themselves have no sleeve or rubbing bearing whatever enables even the

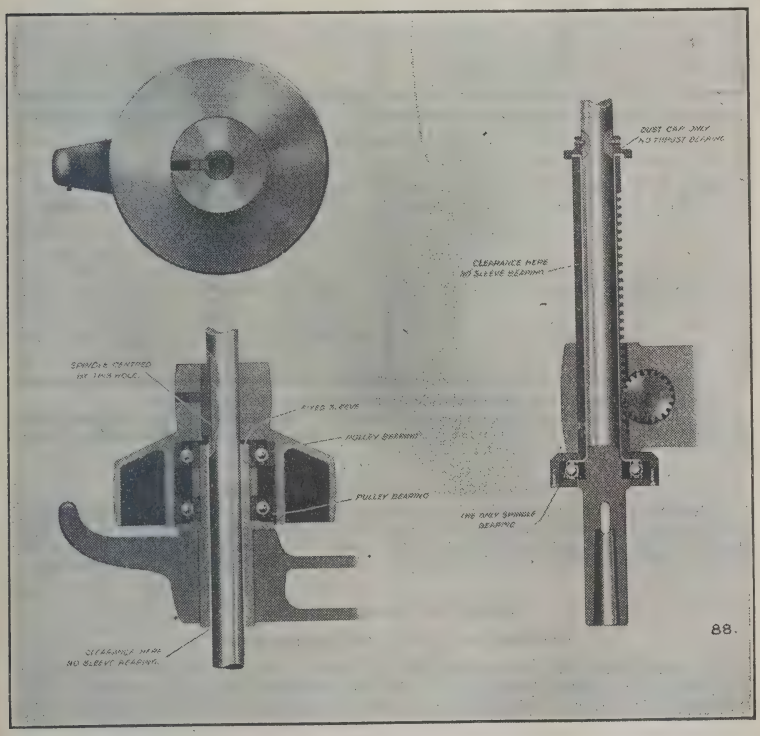

FIG. 29.

smallest sizes of high-speed drills to be run at their proper speeds. At the same time the saving in friction all over the machine permits the feed to be quicker, and enables larger holes to be drilled than has been hitherto possible with ordinary sensitive machines.

The adoption of annular ball bearings enables the latter to be put together in dust-proof housings with a supply of grease which lasts indefinitely. Oiling is neither necessary nor desirable.

As the bearings are interchangeable they can be renewed without trouble; in practice, however, it is a most rare event for a bearing to require renewal.

About four to eight times as many holes per hour can be drilled as on an ordinary sensitive machine. The following particulars show results, using high-speed twist drills:

CAST IRON.

Diam. of Drill.	Speed of Drill.	Time to Drill 1 in. deep.	Diam. of Drill.	Speed of Drill.	Time to Drill 1 in. deep.
		Seconds.			Seconds
¼	2,050	1½	⅝	600	2½
5/16	1,370	1½	11/16	600	2½
⅜	900	2	¾	600	3
7/16	900	2	13/16	600	3
½	900	2	⅞	600	4
9/16	600	2½			

MILD STEEL.

Diam. of Drill.	Speed of Drill.	Time to Drill 1 in. deep.	Diam. of Drill.	Speed of Drill.	Time to Drill 1 in. deep.
		Seconds.			Seconds.
¼	2,050	2⅜	⅝	900	5½
5/16	2,050	2⅔	11/16	900	5½
⅜	900	3⅔	¾	900	6
7/16	900	3⅜	13/16	900	7
½	900	4	⅞	900	7½
9/16	900	5			

The mild steel used in the above tests was 26 tons per sq. in. tensile strength.

The machines are made with one, two, three, and four spindles. The multiple-spindle machines have the spindles considerably farther apart than is usual on small machines, so as to give ample room for operating them.

THRUST BEARINGS OF DRILLING MACHINES.

Vulcanised fibre is being applied to the thrust bearings of light, sensitive drilling machines. Ball bearings cause considerable trouble if one of the balls fractures or chips, and it has been found that a fibre disc answers the purpose admirably. The permeability of the fibre to oil renders it self-lubricating, and its life under these conditions is remarkable. (*Machinery.*)

Portable Electric Drills.

THE WESTOOL MARK 1, 1920 PATTERN DRILL.

This modern heavy duty side spindle drill, figs. 30 and 31 (*The Westminster Tool and Electric Co., Westool Works, Putney, London, S.W.*15), has been designed so as to have a minimum length combined with great mechanical strength, and maximum length of feed. The oval shape of the body renders it specially suitable for corner drilling, and the gear case, top bonnet, and drill body being made from special alloy steel, fitted with ball bearings throughout, enables it to withstand the hard usage and continuous heavy work met with in shipyards, boiler works, railway shops and general engineering works.

All electrical conditions have been carefully considered—the armature and commutator being ventilated by a shrouded fan fitted to the lower end of the windings which produces a strong draught not only round the windings but through the ventilating holes provided in the core stampings.

The reversible switch is of exceptionally strong design with double pole quick make and break action complying with the Home Office requirements.

The gears are so arranged that by changing the two pinions, without alteration of wheel centre,

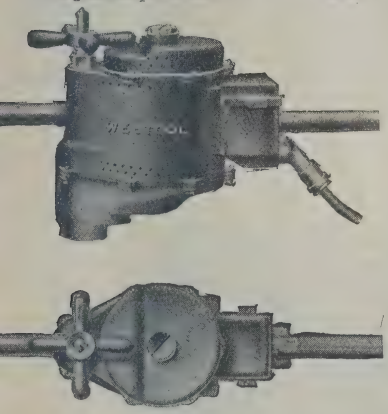

FIG. 30.

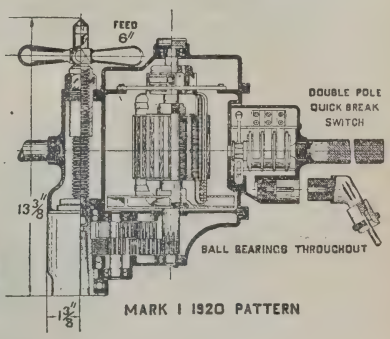

FIG. 31.

two-speed ratios can be obtained—one the standard for ordinary drilling and reamering work and the other giving a slower speed with the full power for tube expanding or tapping.

'WESTOOL' ELECTRIC PORTABLE DRILLS.

Size number	1	2	3
Morse taper	No. 1	No. 2	No. 3
Range of drill bits	$\frac{1}{8}$ in.—$\frac{9}{16}$ in.	$\frac{10}{32}$ in.—$\frac{29}{32}$ in.	$\frac{15}{16}$ in.—$1\frac{1}{4}$ in.

Distance from drill centre to side of case	$1\frac{9}{32}$ in.	$1\frac{5}{16}$ in.	$1\frac{5}{8}$ in.
Approximate weight, lbs.	24	34	58

These tools have been designed to give high drilling speeds when working in modern high speed steels, and have consequently great power for their size. They will drill holes $1\frac{5}{8}$ in. deep in mild steel in one minute at their rated diameter holes. The tools can be used for reaming, tapping, and tube expanding. In the last process the strain on the tool is very considerable but it is successfully met.

THE VAN DORN DRILL.

These tools, fig. 32, are made by the Van Dorn & Dutton Co., Cleveland, Ohio. They are designed so as to be easy to handle, and are light and compact. The machines designed to take drills up to $\frac{5}{8}$-in. diameter may be operated by either direct or alternating current. Another

advantage of the design lies in the fact that the drill spindle is offset, so that holes may be drilled close to a flange or similar projection.

The Gear Case is a light aluminium casting reinforced with ribs to resist distortion. This case is not only an efficient housing for the gears, but forms a grease chamber from which the gears and main spindle bearing receive ample lubrication. Each end of armature shaft runs in a ball journal bearing fitted in a steel housing, and the thrust is also taken on a ball thrust washer. The gear spindles run in high-grade phosphor bearings.

The Gears, accurately generated, are made of special heat-treated steel, hardened and ground.

The Motor is series wound. The adoption of this type of winding renders the speed automatic,

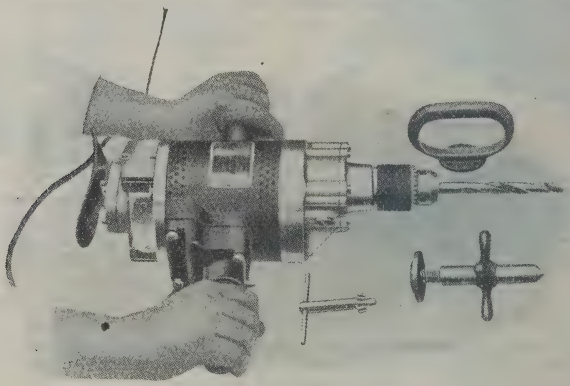

FIG. 32.

the pressure used to force the drill into the work governing the speed of the drill. The armature and field coils are form wound and thoroughly insulated.

The Armature is of the slotted drum type built up of soft steel laminations, these being made from special steel adapted to the purpose and uniformly insulated. On the DC.2 and larger machines the armature is built on a hollow shaft to preserve lightness.

Ventilation.—One of the distinctive features of the Van Dorn drills is the system adopted for thoroughly cooling the motor. It consists of a large aluminium fan of special design, screwed on the armature shaft. It is so constructed and placed in such a position as to draw out the hot air at one end of the machine, to be replaced by cool from the other. A constant draught is therefore maintained, ensuring a low temperature.

The Switch is of the quick-break type with a capacity of 5 per cent. above the duty required. By the use of release attachments the switch has the same rapidity in breaking as in the making contact. The larger sizes are provided with a quick-acting self-releasing attachment.

A Safety Fuse, consisting of a small piece of fuse wire held by screwed terminals, is fitted to machines up to and including $\frac{1}{2}$-in. capacity, and may be quickly replaced if necessary; this prevents the possibility of damage to the machine from overloading or from a short circuit which is generally caused by the operator omitting to clean the commutator.

MINIMUM DRILLING PERFORMANCE OF UNIVERSAL PORTABLE ELECTRIC DRILLS.

Carbon-steel drills in 0·20 per cent. to 0·30 per cent. carbon steel.

Capacity of Tool and Size Drill. In.	Speed.	Rate of Feed. In. per Min.	H.P. at 1 H.P. per Cub. In. Metal Removed per Min.*
$\frac{1}{4}$	800	$1\frac{1}{2}$	0·08
$\frac{5}{16}$	650	$1\frac{1}{8}$	0·10
$\frac{3}{8}$	525	$1\frac{1}{4}$	0·13
$\frac{1}{2}$	375	1	0·19
$\frac{3}{4}$	300	$\frac{1}{4}$	0·23

* Extensive tests have shown this to be a reliable basis for determining power requirements.

Drilling Appliances.

The 'Selson' Gravity Drilling Machine Vice.

In this arrangement, fig. 33, the jaws are opened by sliding them up the angle guides, the maximum opening of the upper jaws being 8 ins., the lower 2½ ins. When the work is set, gravity, supplemented by the pressure of the drill, forces the jaws downwards in the guides, ensuring an absolutely firm hold of the work and making the vice practically an automatic tool.

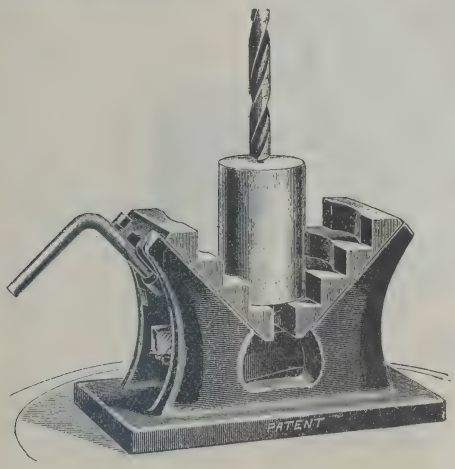

Fig. 33

A slight turn of the handle prevents the work from becoming slack when the pressure on the drill is decreased at the bottom of the hole.

The vice can be used loose on the machine table, except in extreme cases. Slots are, however, provided for bolting it down.

It will securely hold all round work from ¼ in. to 8 ins. diameter. Work is ensured against turning even with slight pressure on the drill. Special shapes are held as firmly as regular ones.

There are but five main parts in the vice, which adds to its simplicity.

Size of base, 12 ins. × 6½ ins. Approximate weight, 45 lbs.

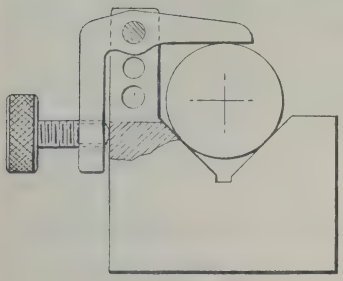

Fig. 34.

V-Block with Adjustable Clamp.

A compact method of fitting a clamp to grip work in a V-block for marking or for drilling purposes, is to make the block with uprights composed of two plates attached to the ends of the block (fig. 34). Three pin-holes are drilled through the uprights, into which an ordinary headed pin is slid to sustain the cranked clamp seen. This is tightened down upon the work by setting up the screw.

(*'Machinery.'*)

The 'Brooke' Quick-Change Universal Drill Jig.

This arrangement (fig. 35) is for the purpose of drilling pin holes in bolts, studs, pins, etc., for split pins, etc. It consists of a baseplate, on which are mounted two pillars carrying, at the top, a steel cross beam, which serves as a clamp for holding the work and also as a guide to the drill by means of suitable bushes. The jig can either be used on a table with a plain surface or bolted down, as required. For plain service tables, a locating pin is supplied to fit the baseplate and hole in the centre of drilling machine table, keeping the guide bush in the cross beam always in line with the drill spindle.

The work is held in a V-block, provided with a groove on each side, fitting the square portions

of the pillars, which thus act as guides, enabling the block to be rapidly adjusted to the required position indicated by pointer and rule, and afterwards locked in place by a small lever instead of the hexagon nut shown in the fig. This block admits bolts from 1½ in. to ¾ in. diameter,

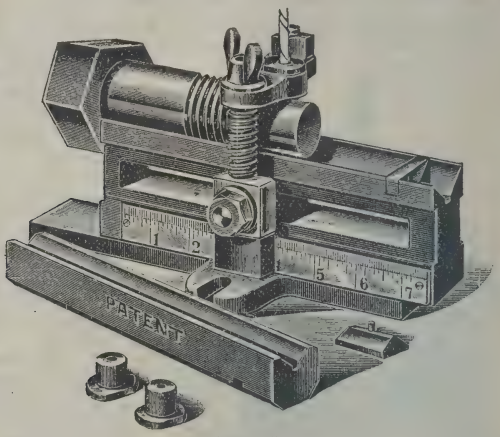

FIG. 35.

and for smaller work an additional V-block is supplied, which fits into the larger one, and can be used for objects down to ¼ in. diameter. For studs and other parallel work, steps are provided on the right of both V-blocks, against which the end of the stud rests.

SCREWING MACHINES.

Figs. 36 and 37 show single- and double-spindle high-speed screwing machines, constructed by Charles Winn & Co., Birmingham. The machines are made in several sizes and are specially designed to give rapid production on repetition work, and are therefore important tools in shops, manufacturing bolts, etc., in large quantities.

The die heads (Winn's Patent) are entirely self-operating, enabling the operator to give his whole attention to the handling of the work; they open automatically when the required length is screwed, and close again ready for the next piece on the return of the saddle—thus in the case of the double-spindle machine, the time taken to screw one bolt is utilised by the operator to feed the other head, so that screwing and feeding go on simultaneously.

The dies, each comprising a set of four chasers, are set for the various sizes of screwings by adjusting the cam ring to markings on the outside of the die head, and as this adjustment is entirely independent of the automatic opening and closing of the dies, any size screwing can be exactly repeated any number of times.

The die spindles are hollow and run in long-capped bearings, which are provided with adjustable thrust collars to take up play endways. The gears are machine cut from the solid blanks, and are protected by a strong cast-iron guard.

The vices are fitted with duplex grips which hold the work truly in line without depending on support from the dies, while, as the jaws come close up to the head, the shortest work can be screwed.

A rotary-geared pump, fitted at the back of the machine, supplies the dies with a continuous stream of lubricant, the swarf and oil being collected in a large tray fitted with a reservoir and strainer.

Fig. 38 shows a larger machine of similar type. It will screw tubes up to 4½-in. outside diameter, and bolts up to 3-in. Whitworth at one cut, and is designed to meet the requirements of dock and shipbuilding yards or general shops in which the work is of a varied nature. The die head is shown fitted with Winn's patent automatic gear, but it is frequently supplied fitted with instantaneous hand-lever releasing motion—the type depending on the character of work to be screwed.

The machine is strongly proportioned, to give rigidity under heavy cutting stresses, while all bearing surfaces are large and are provided with means of adjustment for wear. The drive is by

MINERVA

Bright-Part Coating and Rust Preventive

For coating machinery bright parts to prevent rust during transit and erection.

This article is intended for brushing on the bright parts of machinery, prior to leaving the foundry or finishing shop, to prevent rusting during railing, shipment, storing and erection. It dries almost immediately with a firm, elastic, damp resisting surface that will stand temperatures met with during shipment and will not come off through ordinary handling.

To remove, simply wipe off with a cloth damped in Paraffin, Benzine, Turpentine or Petrol.

CHARLES WINN & CO.'S SCREWING MACHINES.

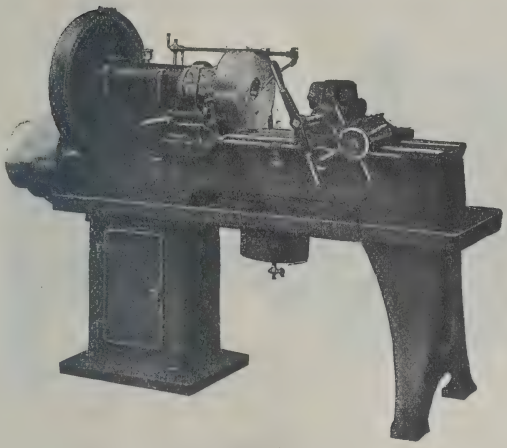

FIG. 36.

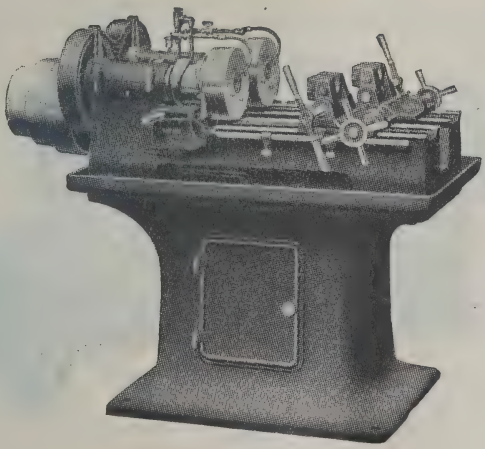

FIG. 37.

CHARLES WINN & CO.'S SCREWING MACHINES.

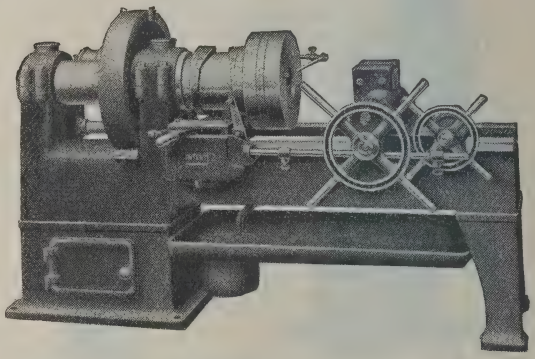

FIG. 38.

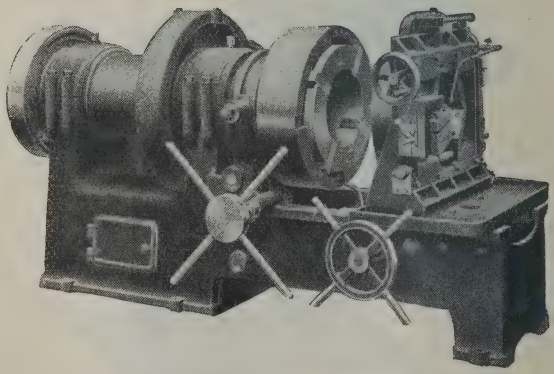

FIG. 39.

a large four-speed cone pulley at the rear through a double train of machine-cut spur gears which are completely protected by a cast-iron guard. The die spindle is hollow right through, and is fitted with adjustable locking rings to take up endway play.

The vice is of massive construction. The jaws, which slide upon square gibs having steel adjustment strips, are fitted with duplex grips which give a wide bearing on the work, holding the same truly in line, without depending on support from the dies; moreover, bends and irregular pieces requiring a narrow grip are provided for by merely slipping out the back pair of grips. In machines of this size, gearing is introduced between the handwheel and vice screw to give increased gripping power. Lubricant is forced upon the dies by a rotary-geared pump, a large tray with reservoir and strainer being fitted underneath the machine to collect the oil and swarf.

Fig. 39 shows a type of machine specially designed for tube works use. It is made in eight sizes, ranging from machines taking from 1-in. tube as a maximum to very heavy machines capable of dealing with tubes up to 13 ins. diameter. The illustration is of the largest size of machine. It possesses several features which make it far more rapid in operation than the machines in general use. As will be seen by reference to the illustration, the work in this case is revolved, the dies being mounted upon the saddle.

The tube is gripped or released while the machine is in motion by a quick-grip chuck (Winn's patent), which operates by the large capstan handwheel in front of the machine. An important feature of this chuck is that it can be very quickly set to take the various size tubes, the jaws being simultaneously adjusted to a larger or smaller size, by setting the cam ring to markings on the outside of the chuck.

The die head is of the adjustable type, fitted with a positive opening and closing action operated by an improved geared segment lever.

With this device the leverage is considerably increased, enabling the die head to be opened and closed with ease; and moreover, in closing, the head automatically locks itself to the same size each time. This feature is a great improvement upon the method of setting the cam to a mark and locking with a nut, which is not only very slow but depends upon the skill of the operator to set the dies to the same size each time.

A pair of self-centring Vee steadies with hardened steel faces are situated at the back of the die head, for the purpose of steadying the tube whilst being cut off.

In the smaller size machines a combined cutting-off and nipple-making slide is carried behind the steadies, but in machines dealing with tubes larger than 6 ins. diameter a plain cut-off rest is substituted for the nipple-making slide.

Provision is made for the easy escape of chips from the working parts of the machine, and a copious supply of lubricant is delivered to the dies and cutting-off tools by a geared rotary pump.

Lubrication.

'SUPER-SCREWOL.'

This is a soluble oil (*Sterns, Ltd.*), specially treated to render it antiseptic so as to conform to the requirements of Government inspectors. It is suitable for screw cutting, drilling, turning and boring, for turret and other lathes, hydraulic machinery, etc. It does not rust, clog or separate. It has no smell, scum, or evaporation, and is free from spirit or ammonia.

MAGNETIC CHUCKS.

The Magnetic Chuck is now largely used for holding machine parts of iron and steel for grinding, turning, and planing operations. Many pieces, such as milling cutters, thin saws, air-compressor valve discs, chain links, etc., can be more effectively held by this method than by any other. Not only is there a great saving in the time ordinarily required for setting up, but the likelihood of distorting the job due to unequal straining of the holding down bolts is eliminated.

It must be understood that the holding power of a magnetic chuck depends as much on the shape and section of the piece to be held as on the magnetic chuck itself. If the piece is small in section the hold will be very light, no matter what the section or intensity of the chuck magnets may be. The hold is entirely dependent upon the number of magnetic lines that can be passed through the section of the piece, and not on the total magnetism that the chuck can produce. Some makers claim a holding power of 100 lbs. per sq. in., this having been attained on a perfectly surfaced cube of Swedish iron applied between the chuck poles. This affords no useful measure of the holding value of a magnetic chuck, as theoretically a small magnet either of steel, wrought iron or even cast iron, if perfect at the joints, would give (on such a cube)

100 lbs. per in. On the other hand, if two such cubes were placed together the pull would not be proportionately increased, as the magnet being small the section of the first cube would absorb all the magnetism it could supply. Thus a chuck, say 30 ins. by 8 ins., which would pull 100 lbs. on any sq. in. of its surface could not, under any circumstances, pull 30 ins. by 8 ins. by 100 lbs., or nearly 11 tons, on its entire surface. The pitch of the poles should be arranged to suit the class of work to be held; if the pieces are of heavy section, the magnet must be of heavy section to get the best results.

Fine Grinding.—For fine grinding it is well to reduce the magnetic pull of a chuck face, either by inserting resistances in the coil circuit, or by the interposition of non-magnetic material

FIG. 40.

between the work and the chuck face. The lighter the pull the more accurate the resultant work. Specially constructed chucks of a very light but even pull are necessary for thin saws, light piston rings, etc. Grinding with water, soda and other liquids makes it absolutely essential that the magnetic chucking apparatus must be impervious to water. In the Humphreys chucks

FIG. 41.

FIG. 42.

FIG. 43.

FIG. 44.

FIG. 45.

one of the leading features is the insulating method employed. The wire itself, before winding, is insulated with a special liquid having very high insulating properties and capable of withstanding weak acids, alkalies, saline solutions, or alcohol. After winding and coating with a special fabric for mechanical protection, the coils are heated to 200°F., and placed in a heated

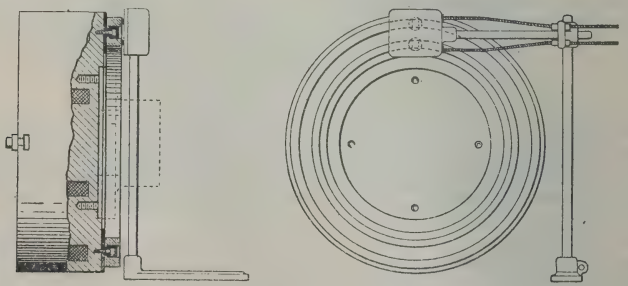

FIG. 46.

tank from which all air and moisture is then extracted. After being subjected to this high vacuum for some time, the tank, without breaking the seal, is filled with a liquid asphaltum compound at high pressure, rendering the coils absolutely proof against moisture, etc. The coils

are then placed in position over the cores of the magnets, and the whole chuck body filled and made solid with the asphaltum compound.

Fig. 40 shows the face of a Humphreys (Pat.) circular chuck suitable for piston rings, saws, milling cutters, and general work. These chucks are constructed in sizes ranging from 6½ ins. diameter to 72 ins. diameter. Other designs of chuck faces for special work are shown in figs. 41, 42, 43, 44 and 45; the finer pole designs being used for very small pieces, and the simpler 8-pole design for larger section pieces.

The method of current supply is shown in fig. 46; this is used for dry grinding only. The chuck is fitted to a lathe or grinding machine spindle exactly as an ordinary mechanical chuck.

The brass slip-ring running with the chuck itself collects the current from a contact box, which is held by a tubular support from the lathe or machine bed. The contact box contains a pair of carbon brushes actuated by springs; these brushes are totally enclosed. The method is simple and effective, especially in cases where the chuck is only used occasionally and the apparatus has to be removed and set up each time. Fig. 47 shows an arrangement adopted by the above makers for both horizontal and vertical machine spindles. A hollow spindle machine

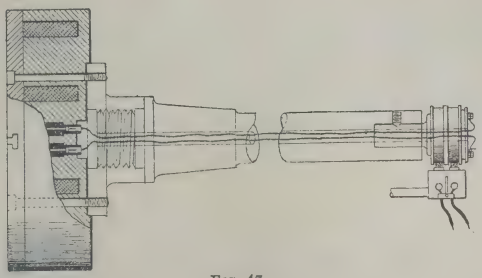

FIG. 47.

is necessary in this case, and the advantage is that all water suds or soda mixture is kept entirely away from the running contacts. The current is carried from the contact rings through the spindle, and is conveyed to the chuck windings by means of a pair of plugs fitting directly into the back of the chuck.

Magnetic chucks are not adaptable to alternating current, and must be used on the voltage for which they are designed. If a higher voltage be applied there is a likelihood of burning out the coils, and with a lower voltage the full power of the chuck is not developed. Fig. 48 shows

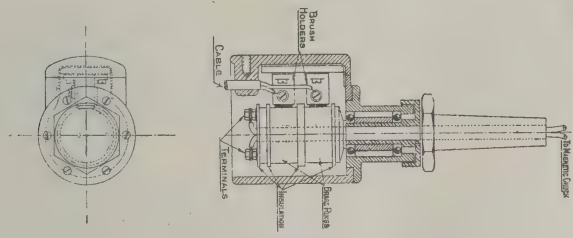

FIG. 48.

the contact arrangement when used with a vertical spindle; it is totally enclosed, the shank is tapered and fitted with a nut to facilitate removal. An oil throw or guard is provided to keep off the bearing oil.

Flat Chucks.—In fig. 49 is shown the details of the 'Humphreys' standard flat chucks, suitable for grinding, planing, and milling machines. These are constructed in sizes up to 72 ins.

by 10 ins. : they are fitted complete with a rise and fall parallel strip and an adjustable end-stop. Movable fingers or clamps may be set to support work set on edge ; these fingers are secured by set screws in a T-slotted bar, which may be fixed conveniently at any height. The end-stop is necessary to take the thrust of a milling or planing cut ; in most grinding operations it is not necessary to use it.

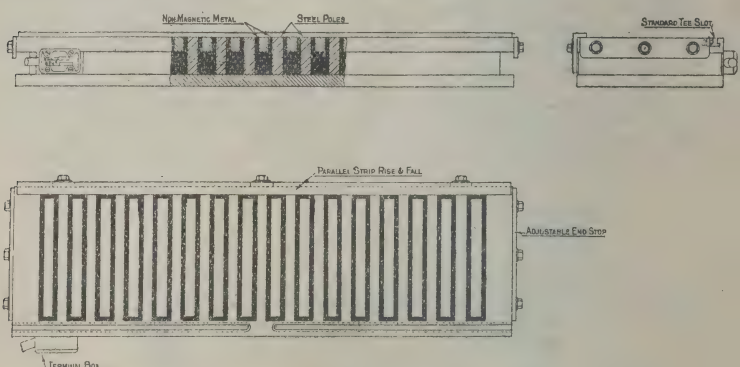

FIG. 49.

Fig. 50 shows a variation of this form of chuck for machining taper pieces. This chuck is carried on a sub-base hinged at one end, and has a fine knurled screw adjustment at the other. The index graduation is in inches per foot. When the setting is at zero the chuck can be used for ordinary flat work.

Switches.—One of the most important pieces of apparatus in connection with the magnetic chucks are the switches used for operating. When the current from a magnetic chuck is cut off,

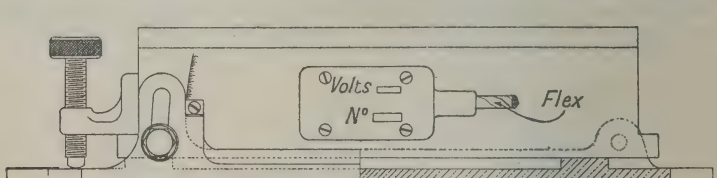

FIG. 50.

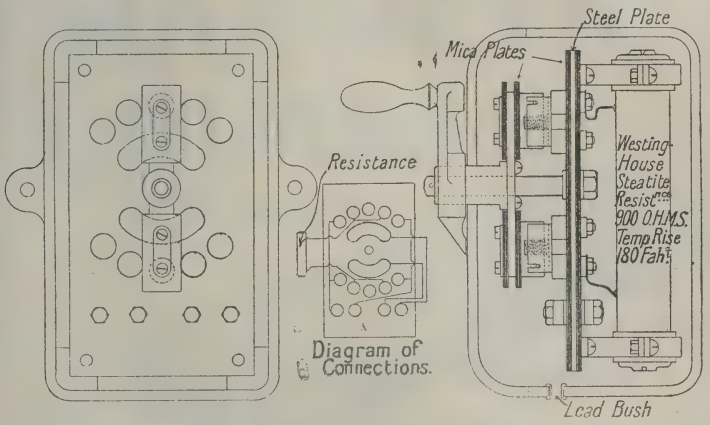
a back current is induced in the chuck coils. This induced current is of a very high voltage, and if the switch gear is not perfectly designed to deal with it, the insulation of the chuck, however well designed and carried out, will inevitably break down. The switch must be double-pole, that is, it must operate on both the positive and negative supply wires at the same time, also it must be capable of admitting current to the chuck in either direction, and in order to deal with the induced back current when switching the chuck off, it must be provided with a non-inductive resistance which must automatically be put in circuit with the chuck prior to breaking the circuit. Fig. 51 shows the 'Humphreys' No. 7 Demagnetising Switch. To operate it the switch handle must be moved past the 'Off' position and held momentarily on the 'Reverse,' going back quickly to the 'Off' position ; this is for the purpose of demagnetising the chuck sufficiently to allow of the work to be easily removed. The view on the left of the figure shows

the arrangement of contacts. For very large chucks a special oil-break switch is furnished; the method of operation is similar to that of the No. 7 switch, but the contacts are immersed in oil and the non-inductive resistances are carried in a separate iron case forming the base of the switch.



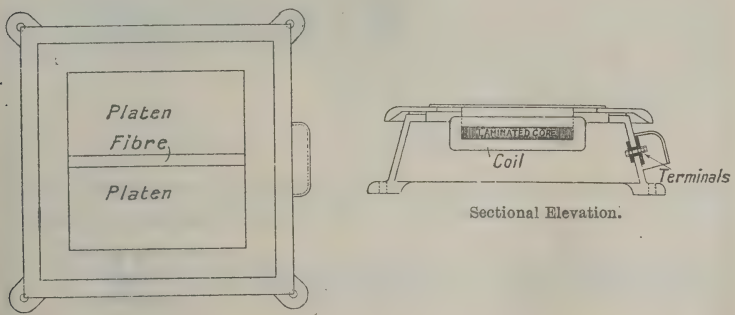


FIG. 51.—No. 7 Demagnetising Switch, Slow Break, Capacity 2 Amps.

The sectional view on the right-hand side of the figure shows the non-inductive resistance. The main plate is mica insulated; in several sizes of switches this main plate consists of a slab of slate.

The arrangement of the connections, etc., is shown in the central view of fig. 51.

Plan.

Sectional Elevation.

FIG. 52.

Demagnetisers.—Consequent on the use of magnetic chucks is the permanent magnetic condition imparted to the finished work, which with milling cutters and similar articles would prove a decided objection. A magnetised milling cutter would collect to itself the cuttings as produced, and though this might not impair its efficiency as a cutter, it would be a source of annoyance to the operator. Fig. 52 shows a sectional elevation and plan of a demagnetiser by

J. H. Humphreys & Sons. There are two working platens, and all that is necessary is to pass the work over these platens, when it will be instantly demagnetised. As shown in the section drawing, immediately under the working platens is a powerful laminated magnet, which takes from the transformer a low period, low voltage, alternating current. The transformer carries

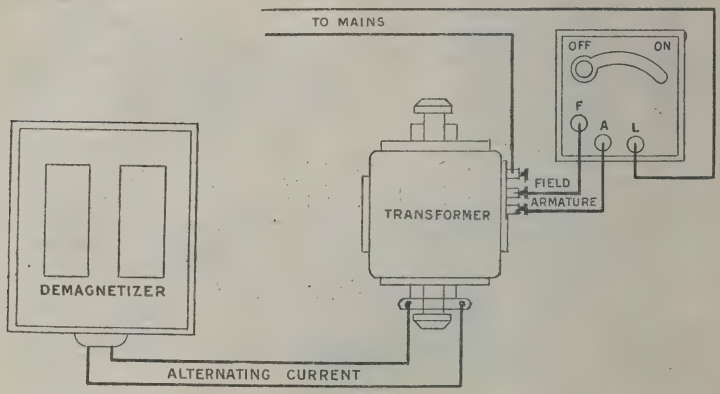

FIG. 53.

a double winding, one connected to a pair of slip-rings at one end of the shaft, the other being an ordinary motor winding which is connected to the mains through a starting rheostat exactly as an ordinary electric motor. This arrangement is very convenient, no fixing is required, and the demagnetiser can be placed in any position independent of the transformer.

The whole apparatus, fig. 53, includes demagnetiser, rotary transformer, and starting rheostat.

Electro-Lifting Magnets.

An electro-magnet attachment to overhead yard cranes facilitates the picking up of scrap and pig iron and is also useful for charging boxes with these in steel works. The attachment when provided with a skull cracker is used for breaking up scrap and pig. The ease with which the cracker can be picked up and dropped without the help of other labour than the crane man himself, also the speed of hoisting and freedom from accidents are factors which have contributed to the development of this gear.

A 5-ton crane to lift at 20 feet per minute takes about a 10 h.p. motor.

Milling Speeds and Feeds.

With regard to milling speeds and feeds, the amount of reliable experimental data available is very meagre and the machinist must for the present content himself with compiling data for himself. The subject is very complicated, and he will require to make the fullest possible observations at least at the commencement. For this purpose, he will note the following : dia. and width of cutter, revs. per min., depth and width of cut, feed in inches per min., number of teeth in the cutter, type of cutter, feed per tooth, material and nature of the work. To measure the capacity of the machine by the feed per tooth alone may give misleading results.

Tests made on a No. 22 'Single Pulley' Horizontal Milling Machine made by Messrs. Alfred Herbert Ltd., Coventry.*

P. V. Vernon (Alfred Herbert & Co.) before the Manchester Assoc. of Engrs. 1912.

Metal Hand Sawing.

Experiments undertaken in France to determine the best method of sawing metal by hand indicate that it takes less time to saw off a rectangular bar of steel when the saw is moved parallel to the shorter side of the rectangle than when it moves parallel to the longer side. It was also found that the shorter the stroke of the saw, the quicker would the bar be sawed off. In sawing off a rail by a nack saw, it required nearly three times as long when the stroke was 4 ins. in length, as compared with when it was somewhat less than ½ in. in length. The work performed per minute decreases regularly for each ½-in. increase in the length of the stroke. It is also stated that by holding down the end of the saw farthest away from the workman—not by hand but by a weight—the time required for sawing through a bar is shortened, a thinner blade can be used, and a better surface on the ends of the sawed-off bar is obtained.

Wood-working Machinery.

The following list, which gives the various sizes of motors it is advisable to put down for the machines mentioned, allows for the motors being capable of giving 25 per cent. overload for not less than 1½ hour, without any undue heating, and it is always advisable to leave this amount of margin to meet extra heavy cuts, which a machine has to cope with fairly often in this class of work. The figures given in the list are based upon the average work found in the particular shops where the machines are generally used, and in cases where extra heavy duty is required regularly an increase in the size of motor will be necessary. The type of motor chosen has a certain influence upon the amount of marginal power, and this point requires careful attention.

When motors are direct coupled it is advisable to use a flexible coupling in order to avoid shock on the motor due to fluctuating loads.

The foregoing powers assume that the cutters or saws are running at about standard speeds, and are in good working condition; also it is assumed that the rate of feeding is about the standard, and not speeded up above the makers' speeds. It is, of course, understood that any machine, particularly saw benches, can be fed until they take an abnormal amount of power, but the intelligent workman can so humour the feed without losing time that he gets almost the maximum amount of cutting done with the minimum amount of power expended.

The power absorbed per sq. ft. surface sawn per minute varies very much in some instances and it is impossible to get anything like an accurate figure, as there are so many variable factors; thus, the amount of power absorbed by the saw increases or decreases according to the amount of set given to the teeth, and the set requires to be varied considerably according to the class of timber to be sawn: even in the same class of timber the grain in one part of the cut might be such that it closes in on the saw more than in another part of the cut.

The speed of the cutting edge and the angle, in knife tools, and the shape of saw tooth, speed, angle, and thickness of saw, in saws, has a great influence on the amount of power a machine will absorb when doing certain classes of work.

The following list gives the various speeds, etc., of certain machines, the information being the latest practice.

Circular Saws for ripping, soft wood	9,600 to 11,000 ft. per min. (peripheral)	
" " hard "	9,600 to 11,000 "	"
" " ordinary cross-cutting, soft	10,000 "	"
" " " " hard	8,000 to 10,000 "	"
" " (Hollow ground)	10,000 to 11,000 "	"
Ordinary plain Band Saws, soft wood	4,300 to 5,000 "	"
" " hard wood	4,300 to 5,000 "	"
Deal cutting Band Saws, hard or soft	6,500 to 7,000 "	Specially designed
Log Band Saws	6,500 to 8,000 "	machines

Reciprocating Mortising Machines:

Mortising up to	1/8 in. wide,	4½ ins. stroke	(not graduated), crankshaft speed	400 r.p.m.
" "	1 "	" "	"	350 "
" "	1¼ "	6 "	(graduated) "	270 "
" "	2½ "	6½ "	" "	255 "
" "	3 "	7 "	(not graduated) "	160 "

Vertical Deal Frames (Single):

To take timber 12 ins. by 6 ins.	Continuous Feed "	300 "
" " 18 ins. by 6 ins.	" "	250 "
" " 28 ins. by 5 ins.	" "	200 "

Vertical Deal Frames (Double):

To take timber 20 ins. by 6 ins.	" "	225 "
" " 24 ins. by 6 ins.	" "	200 "

Horizontal Saw Frame (Single blade):

To take timber 24 ins. square	2 ft. 6 ins.	stroke	(balanced) "	320 "
" " 30 "	"	"	" "	300 "
" " 36 "	"	"	" "	280 "
" " 42 "	"	"	" "	260 "
" " 48 "	"	"	" "	230 "

Double Equilibrium Deal Sawing Frames (balance swing frames):

To cut 2 deals up to 14 inches × 5 inches, 350 revs. per min. (of crankshaft).
" " 18 " × 6 " 300 " " "
" " 24 " × 7 " 250 " " "

Bandsaws, blades running on wheels up to 3 feet diameter:

For sawing very hard ivory, etc., traverse of saw blade per minute, 750 feet.
" iron " " " " " 250 "

Vertical Spindle Moulding Machines:

Single Spindle (light type)	5,000 to 6,000 revs. per minute.
Double " (")	5,000 to 6,000 " "
Single " (medium type)	4,000 to 4,500 " "
Double " (")	4,000 to 4,500 " "
" " (heavy type)	3,500 to 4,000 " "

High speed Four Cutter Moulders:

Bottom spindle	4,000 revs. per minute, 6 ins. dia. cutting circle app.
(2) Side spindles	4,000 " " 6 " " "
Top spindle	5,000 " " 6 " " "

The above represents the average machine up to 12 ins. by 4 ins., and give approximate peripheral cutting speeds of :—bottom spindle, 6,300 ft. per min.; side spindle, 6,300 ft. per min.; top spindle, 7,800 ft. per min.

The extra speed given to top cutter spindle is because this cutter spindle has the heaviest work to do, having to reduce the timber to an even thickness and a given size.

Surface planing machines . . .	5,000 to 5,500 ft. per. min. of cutting circle.
Surfacing and thicknessing machines (combined)	5,000 to 5,500 „ „ „

The above instances are for average cases, and may be accepted as good standard practice at the present time.

Tenoning Machine (light)	4,500 to 5,500 ft. per min. of cutting circle.
„ „ (heavy)	3,500 to 4,500 „ „ „ „
Fret Saws	1,200 revs. per min. 1¼ in. stroke.
Carving Machines (light) . .	8,000 revs. per min. of spindle.
Single Spindle Dovetailing Machines	5,000 to 6,000 revs. per min. of spindle.

Boring Augers (ordinary):

Up to 1 in. diam., 1,800 to 2,000 r.p.m. Up to 2 ins. diam., 1,000 r.p.m. Up to 3 ins. diam., 750 r.p.m.

Emery Wheels, for saw-sharpening, etc., 4,500 to 6,000 feet periphery velocity.

Hack-Saws.

Insufficient attention is given to the lubrication of hack-saws while cutting. It is as necessary to apply ample lubricant to hack-saws as to any other cutting tool, and many power hack-saw blades merely rub their way through stock because the first few strokes have destroyed the hardness of the teeth, owing to the temperature attained in the absence of lubricant.

Hand hack-saw blades generally suffer the same careless treatment accorded to files. The proper use of these hand tools is not impressed upon the semi-skilled labour of to-day, and the hack-saw bills of many firms could be reduced considerably if more attention were given to this matter.

Power Losses in the Machine Shop.

Engine friction, 10 per cent.; line shafting, 15 per cent.; belts and pulleys, 15 per cent.; empty machines, 15 per cent.; cutting metal, 45 per cent.; total, 100 per cent.

Even this efficiency is probably only realised when everything is working at full capacity. Of all metals cut in the machine shop, cast-iron is said to absorb least power per unit of weight removed, while the harder steels require the maximum. Thus, to remove 1 lb. of cast-iron per hour requires the continuous expenditure of from 0·15 to 0·30 h.p., or, say, an average of $\frac{1}{10}$ h.p., where steel calls for $\frac{1}{3\cdot5}$ h.p. An average lathe will cut 10 to 20 lbs. of cast-iron per hour and absorb ¼ to ½ h.p. in useful work, and similarly steel will be removed at a rate of 5 to 10 lbs. and demand ½ to ⅔ h.p. Much also depends on the condition of the machine itself, which may increase its demand for power from 0·36 to 2·3 h.p. very quickly, simply from a dry main spindle. A lathe run without cut may absorb 0·04 to 0·16 h.p., and this will amount up to 0·3 or 0·4 simply by tightening the work in the centres. A large 84-inch wheel lathe has been found to absorb 1·75 h.p., and when cutting, 5·8 h.p. on heavy work.

Planers use ·035 h.p. per pound of cast-iron removed per hour, and 0·065 h.p. per pound of steel, and it may remove 20 lbs. of soft steel or 30 lbs. of cast-iron per hour. Ordinarily, however, the machine would not consume 1 to 1·3 h.p., as these figures would indicate, but only about ½ h.p. Adding for the machine will probably show an average power of 1·0 h.p. in ordinary work.

Felt Wipers on Slides.

To prevent grit working under the slides of machine tools owing to rounded corners, felt wipers may be fitted as shown in fig. 54. The felt is held in place by 1-in. angle iron secured to

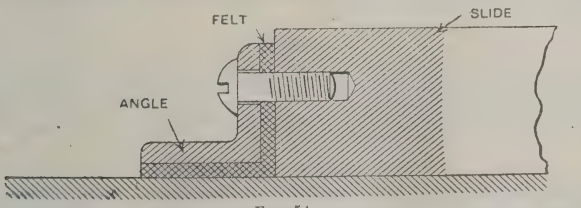

Fig. 54.

the slide by button-head screws. In practice the felt retains the oil and helps to keep the slide lubricated. (*Machinery.*)

TOOL STEEL AND TOOLS.*

Treatment of Carbon and High-Speed Steel Tools.

CARBON STEEL.

The term carbon steel has been generally applied to 'straight carbon' and 'carbon-alloy' steel. The former is obtained directly from blister steel, which is melted in crucibles, poured into a cast-iron mould and cooled. Subsequently the ingots are retreated, hammered and rolled to the desired shape and size. The carbon-alloy is obtained by adding small quantities of tungsten, chromium, silicon, etc. The latter steel has distinct advantages over the former in that it is easier to forge, is less liable to failure in hardening, and has a greater cutting capacity. The chemical composition of a representative tool of the latter class is given below.

Chemical Composition of Ordinary Carbon Tool Steel.

Carbon, 1·1 per cent.; manganese, 0·35 per cent.; silicon, 0·17 per cent.; phosphorus, 0·018 per cent.; sulphur, 0·015 per cent. The sulphur and phosphorus are undesirable quantities, the former producing brittleness when hot or 'hot shortness,' and the latter 'cold shortness.' The silicon and manganese facilitate melting and forging, and improve the quality of the finished steel. The hardness of the steel chiefly depends upon the carbon contained in it. The various tools contain different percentages of carbon to suit the work they have to do. Thus, tools subject to sharp blows should contain a low percentage of carbon, and keen-edged tools a high percentage. The carbon contents for different classes of tools are as follows:—

Tools such as snaps, hammers, drifts, stamping dies, contain about 0·65 per cent. carbon. Smiths' tools, hot and cold sets, swages, punches, shearing blades, cold chisels, miners' drills, minting dies, contain about 0·7 to 0·8 per cent. carbon.

Large milling and other circular cutters, very heavy lathe tools, drills, taps, screwing dies, reamers, contain about 1 per cent. carbon, whilst the smaller and lighter varieties of cutters, turning and similar tools, drills, and reamers, contain from 1·1 per cent. to 1·3 per cent. carbon.

HARDENING.

Hardening is effected by heating the tool to a colour between a dull and cherry-red; that is, between a temperature of 1,365° F. (740° C.) and 1,400° F. (760° C.), and immediately quenching it in water, or in a suitable bath so that the temperature is at least lowered to 390° F. (200° C.), but preferably to a normal temperature of about 60° F. Some tools, depending on their composition, will harden a few degrees below 1,365° F. and some require a slightly higher temperature. The upper limit must not be exceeded, otherwise the steel becomes coarse and weak, but providing the temperature is kept within the range the steel is apparently uninjured. The lower hardening temperature, or what is called the 'critical point,' must be reached, otherwise the steel after quenching will be too soft for cutting metal.

TEMPERING.

This is done by heating to a temperature between 390° F. (200° C.) and 600° F. (315° C.) and cooling slowly. The higher the tool is heated within this range the softer it becomes. It is of the utmost importance that the tool should be uniformly heated, and quenched, otherwise some parts will be harder than others and internal stresses set up which will produce warping and cracking. To minimise any irregularity in heating formed cutters, modern practice is to heat these in a bath of molten metallic salts which is maintained at a constant temperature by gas or oil jets.

ANNEALING.

Irregular annealing is responsible for much warping and cracking, and it is advisable that formed cutters should be carefully annealed before forging, and even again before being hardened, so as to remove any initial strains and strains produced in machining. These precautions as to annealing should be observed with all classes of steels.

SELF-HARDENING OR MUSHET STEEL.

This class contains on the average about 5·5 per cent. tungsten, 2 per cent. carbon, 1·5 per cent. manganese, 1 per cent. silicon, and 0·4 per cent. chromium. As in the case of high-speed steels the proportions of the various elements have a most pronounced effect on the quality.

FIRTH'S

'SPEEDICUT'

HIGH SPEED

TWIST DRILLS

SPEED UP PRODUCTION

Their toughness and hardness enable them to stand abuse and resist wear.

They are made of the famous 'Speedicut' High Speed Steel, which gives higher speeds and greater feeds.

Stringent inspection tests ensure individual perfection.

They are the product of experience extending over three generations.

LARGE STOCKS ARE CARRIED FOR IMMEDIATE DELIVERY.

THOS. FIRTH & SONS LTD.
SHEFFIELD

The self-hardening property of this steel principally depends upon a high percentage of manganese or chromium in combination with tungsten or molybdenum. Such steel is hardened by heating it to a bright red colour (about 1,500°F.) and allowing it to cool. If heated much above this temperature it will crumble in forging, and its cutting capacity is permanently impaired. When cold it is very hard, and retains its cutting edge much better than carbon steel tools.

High-Speed Steels.

High-speed steels are also self-hardening, but are usually forced in cooling by an air blast or by quenching in oil or other medium. The elements of this steel are very similar to some of the older types of self-hardening steels, but they contain much more tungsten and chromium and about one-third the quantity of carbon. Several old self-hardening steels had all the desirable elements and proportions of a high-speed steel, and it was due to the supposed 'overheating' of such steel that its latent cutting capacity was revealed, and not to any new properties or proportions.

Broadly speaking, there are two classes of this steel, viz., *ordinary* and *new* high-speed steel and for these Mr. F. W. Taylor gives the following chemical composition :—

Chemical Composition of Ordinary and New High-Speed Steels.

Class of Steel.	Tungsten. Per cent.	Chromium. Per cent.	Carbon. Per cent.	Manganese. Per cent.	Vanadium. Per cent.	Silicon. Per cent.
Ordinary .	8·0	3·8	1·85	0·30	—	0·15
New or modern	18·91	5·47	0·67	1·1	0·29	0·043

The carbon contents in the ordinary high-speed steel is high, and the principal difference between the ordinary and new high-speed steels is that the latter contains a quantity of vanadium. The addition of vanadium raised the 'critical point' and enables the tool to withstand a higher temperature due to an increased speed of cutting. Tools of this steel are harder and retain their cutting edges longer than ordinary high-speed steel tools. They are therefore particularly suitable for cutting very hard metals, such as railway and car tyres, which have become very hard with usage, manganese steel castings, chilled rolls, etc. A tool containing 0·25 per cent. of vanadium lasted twice the time of a similar tool containing no vanadium, whilst Mr. J. M. Gledhill points out that by substituting 2 per cent. vanadium for chromium in a steel, good results were obtained when tried on medium steel, but were no better than the steel containing the much cheaper element chromium.

A steel may therefore be made of the best quality of material, but unless the elements are properly proportioned and care and skill be exercised during melting to ensure a proper mixing and avoid 'dryness' (a brittleness produced by retaining the steel in its melted state for an undue length of time), it may fall short of a first-class steel. As the percentage of the vital elements decrease, the difficulties in successful melting and mixing increase, and the most satisfactory steel to suit the various conditions prevailing in practice can only be obtained by prolonged experimenting.

To Identify High-Speed Steel Scrap.

The spark from high-speed steel ground on an emery wheel is a dark-red spark that is inclined to scatter, while the spark from ordinary carbon steel is much whiter and is not inclined to scatter. The sparks from high-speed steel are about the same colour as from cast iron, but are much finer.

Annealing.

This process is best accomplished by placing the tools in a sealed oven, furnace, or muffle where they are uniformly heated by radiation. By excluding the air, and preventing the flame impinging on the steel, scaling is avoided and the fine cutting edges preserved. The furnace should be heated in such a manner that in about two hours' time it attains a temperature of 1,544°F. (840°C.), or very slightly higher, and should be steadily maintained at this temperature for about two hours. The heat is then cut off and both furnace and tools are allowed to cool slowly.

To release the furnace during the cooling process some smiths bury the articles in lime, powdered charcoal, soot, or coarse sawdust of some particularly hard wood. The bed in the latter case should be about 24 inches deep and contained in a box having an airtight lid. The articles when dropped on the top of the sawdust and covered with the lid work their way slowly down.

Should such a furnace not be available the tools may be placed in an iron pot or pipe and packed tight with steel cuttings or lime. The pot is then sealed with fireclay and raised to the above temperature at which it is retained for about eight hours before it is placed in charcoal ashes to cool. Good results are obtained from this process, but it is exceedingly slow, and it is doubtful if any advantage is obtained by prolonging the treatment after the annealing temperature has been attained throughout.

Forging.

If a piece has to be cut from the cold bar, this should be done before nicking the bar all round, otherwise small cracks are likely to be started. Preferably the bar should be cut through at a forging heat. In forging, heat the tool slowly and uniformly (without the blast) to a dull red, then raise quickly to a bright red or yellow heat (1,800° to 1,900° F.), when it can be easily and rapidly manipulated. To prevent cracks, hammering should cease as soon as the heat has fallen to a medium red (about 1,400° F.). The steel may be rapidly reheated from this temperature for subsequent forging without any ill-effects. On account of ease and economy in forging, together with general utility and efficiency in cutting, a roughing tool is recommended. This form of tool can be quickly forged by first cutting the required length from the bar and afterwards forming the front, side and top angles by simply jumping the nose. This shape gives the minimum of waste material.

Hardening.

A temperature of 2,000° F., which is ruinous to other steels, gives this steel the property of resisting abrasion at a higher temperature. It is therefore capable of retaining its cutting edge at the high temperatures accompanying high speeds of cutting. This quality, which has been termed 'red hardness,' is not possessed by other steels. In hardening high-speed steel it is slowly pre-heated (in order to obtain a uniform heat throughout) to a medium red (about 1,550° F.), then quickly raised to the following temperatures :—Ordinary high-speed and molybdenum steel from 2,000° F. to 2,200° F. (yellow or lemon heat), vanadium steel from 2,200° F. to 2,350° F. The lower figure is recommended for oil hardening and the higher for air hardening. When the heating is done in the smith's fire, obtain a good, deep bed of small coke or soft coal and preheat the tool by laying it in the fuel at some distance from the hottest part till the fire is thoroughly blown up. To ensure uniformity the tool during both stages of heating should be frequently turned round. Some smiths prefer to obtain final heat by placing the tool within a piece of scrap piping which is maintained at the required temperature by the surrounding fuel on the hearth. Except for the simplest form of tools such as those of the lathe type, the smith's hearth is unsuitable. Formed tools such as milling cutters, hobs, reamers, etc., are best heated in gas, oil or coke-fired muffle furnaces. Modern furnaces for this work usually have two chambers, i.e., an upper in which the cutter is pre-heated, and a lower chamber in which the cutter is raised to the final temperature. Another method of raising the cutter to its final heat is to immerse it in a mixture of molten metallic salts (barium chloride, etc.). The bath is heated and maintained at any desired temperature by passing an electric current through it. As the heat generated varies as the current passes through the circuit the arrangement is ideal for obtaining uniform conditions. The first cost, however, is large, and attempts have been made to obtain similar results from gas-heated salts in graphite crucibles. Trouble arises in the latter device through oxidisation : particles of iron oxide floating on the surface are inclined to adhere to the tool and produce soft spots.

Many have an idea that it is impossible to injure high-speed steel by overheating. This is certainly not the case. If an ordinary high-speed steel tool be heated to 2,400° F. and cooled in an air blast, its fracture will show a very coarse grain.

Once the final temperature has been attained the tool should be immediately withdrawn, as prolonging the treatment, even without raising the temperature, injures the steel and reduces its cutting capacity.

'Pack' Hardening.

It requires a man with considerable experience to harden successfully large high-speed steel milling cutters or hobs, and also a first-class furnace designed for this purpose. The disaster attending repeated attempts to do this has caused some hardeners to resort to 'pack hardening' and possibly the desire to get away from scaling effects has also had something to do with this innovation. In this process about a 1-in. layer of charcoal (¼-in. lumps) is made in the bottom of a cast steel box. Over the charcoal is placed a perforated plate which supports the cutters, but there is no charcoal against the cutters, etc. When several cutters are packed in the box these are separated by asbestos. When charged a lid is placed on the top of the box and sealed with clay. The box is then placed in a suitable furnace and the temperature raised to 1,250° C., and held at that for an hour or two, depending on the time required to thoroughly heat the contents. The cutters are cooled in hot oil or metallic salts in the usual way.

The object of the charcoal is to consume the free oxygen in the box before the steel gets sufficiently hot to scale. Scale is oxide of iron, and will not form if there is no free oxygen, so that however hot the steel may get, it cannot scale.

Tools or cutters which have to be rehardened after having been in use should be annealed prior to this operation, and thereby relieve the internal strains.

Before attempting to harden steel, it is advisable to remove by grinding or machining the black scale (oxide of iron) on the bar or forging, as immediately adjoining it is a thin film of decarburised material, which cannot be altogether avoided in the manufacture, and which will not be hardened.

Quenching.

Uniform cooling is just as essential to the successful treatment of steel as uniform heating, providing this is done it does not matter whether the medium is an air blast, oil, or water. To quench high-speed steel in water, however, is liable to produce cracks, and this is particularly the case in formed cutters where it is impossible to obtain uniform cooling by such a rapid process. Tools of the lathe type are usually cooled in a strong air blast, whereas formed cutters are generally quenched in a bath of salts about 500° F. or in rape or whale oil at a temperature of 250° F. and afterwards cooled in cold oil. The oil cooling gives a clean smooth surface to the cutter.

Quenching Medium.

After heating, it is usual to quench this steel in water, brine, oil, metallic salts, molten lead, etc., depending on the size of the tool or purpose for which it is intended. The function of the medium is to abstract rapidly the heat from the steel, as it passes through the critical range, and nothing more than this. Water therefore, on account of its mobility, makes an excellent cooling medium. The colder the water, and the more rapidly it is circulated, the greater the hardness will be. Cold water which has not had the chill taken off is very liable to produce cracks, whilst with boiling water it is impossible to harden at all. In the latter case a jacket of steam forms between the tool and the water, and cooling is retarded. It follows, therefore, that different degrees of hardness can be obtained by having the water at different temperatures. To raise the boiling-point, salt (as much as the water will carry) is frequently added, and for general purposes such a mixture at 40° C. (104° F.) is quite good. Keep the liquid clean and free from grease or oil. A great deal of nonsense has been spoken and written on the relative merits of quenching mediums, and to Mr. S. N. Brayshaw, M.I.Mech.E., especial credit is due for exploding many of the fantastical theories on this subject. According to Mr. Brayshaw, the ability of a liquid to bring a body immersed in it to its own temperature depends upon the following properties: (1) Specific Gravity, (2) Specific Heat, (3) Boiling-point, (4) Thermal Conductivity and (5) Fluidity.

Specific Gravity.—The specific gravity determines the weight of liquid in contact with the tool being quenched.

Specific Heat.—The heat required to raise the temperature by a given amount, of a pound of different liquids varies enormously. If a red-hot tool weighing 1 lb. be immersed in a gallon of water weighing 10 lbs., the water quenches the tool, and its own temperature is raised about 12° C. in so doing, but if immersed in 10 lbs. of mercury, which has a very low specific heat, the temperature of the mercury rushes up more than 200° C.

Boiling-point.—When a tool is quenched in water or oil, a jacket of steam or vapour may be instantly formed, and this retards the cooling very greatly. Liquids, like solids, vary in their ability to conduct heat, but a deficiency in this respect may be compensated for by motion in the liquid.

Fluidity.—The ability of a liquid to circulate freely is one of the most important factors as regards quenching. The agitation may be caused by moving the tools about rapidly in the liquid, or by directing jets upon them.

Water.—The fact that its thermal conductivity is very low is counterbalanced by its fluidity. The higher the temperature of the quenching water, the more nearly does its effect approach that of oil, and if boiling water is used it will be even more gentle in its action than oil.

The Boiling-point of Water in relation to its Quenching Capacity.

If ordinary tool steel could be very rapidly quenched by any means to a temperature of 100° C. it would harden perfectly; but water at 100° C. (that is, boiling water) is incapable of quenching steel rapidly, and the nearer the boiling-point is approached, the worse it becomes for quenching purposes. When a red-hot tool is immersed in water, steam is generated around the tool, keeping the water away from it and interfering with the quenching. If the water is boiling, the tool is completely jacketed.

The Effect of Stirring during Quenching.—The tools cool much more quickly if they are stirred, or, what amounts to the same thing, if the water is projected in a stream upon the tools.

The Addition of Acid or Salt to the Quenching Bath.—The addition of sulphuric acid increases the conductivity of the water, but the gain from this cause is small in comparison with rapid circulation of water.

It is sometimes stated that sulphuric acid is added to prevent hardening cracks, but this is inconsistent with the other idea that it is used to obtain a greater degree of hardness. If the liability to crack is reduced, it is because the acid has made the quenching bath more gentle in its action, and thereby reduced the hardness.

Seasoned Water for Quenching.

Water ordinarily contains air dissolved in it, and this air is expelled when heat is applied. For this reason water which has recently been boiled and allowed to cool again, may be expected to quench the steel with greater rapidity and uniformity.

Quenching in Oil.—It is necessary in some cases to quench in oil, although it should be avoided wherever possible. Oil to one specification is not always the same, and even if it were, considerable changes are brought about with use, and its quenching power soon becomes different to that of new oil.

Quenching in Fusible Salts.—The ideal quenching liquid would be one which, at a temperature of say 100° C., had sufficient quenching power to cool steel so rapidly that it would harden thoroughly.

Experiments have been made by Mr. Brayshaw with chlorides, fluorides, carbonates, and other compounds, in order to find a 'melt' for quenching.

Such a 'melt' or mixture of salts differs from that used in the salt bath as ordinarily understood, in the fact that the salt bath commonly consists of a mixture of chlorides which are liquid at a red heat, and in which tools are immersed in order that they may be raised to the temperature necessary for hardening. The 'melt' now under consideration is primarily not for heating, but for cooling the tools, although it may be remarked incidentally that such a 'melt' may usefully be applied for the tempering of tools after they have been hardened.

The endeavour was to find a mixture, free from water, which would be liquid at a temperature as low as possible, have a high specific heat, and should be obtainable at reasonable prices.

A mixture known as 'Quenchite' resulted. It is liquid at 135° C. (275° F.), and at this temperature it is almost as fluid as water. It quenches steel very rapidly, has a very high boiling-point, and consequently the liquid is in direct contact with the steel almost from the moment of immersion.

The temperature of 135° C. is, however, so high that 'Quenchite' is only suitable for hardening small or thin articles. Small cutters and long reamers or taps can be quenched in it to give a glasshard surface, and with practically no warping or change of shape, but it is not sufficiently severe in its action to give the necessary hardness to a sufficient depth in the case of large tools in which there is a considerable body of steel behind the cutting edge.

Manner of Quenching.—In order to secure uniform cooling and absence of warping, all sorts of dodges are resorted to by hardeners. In the case of small articles, these are dipped bodily into the medium, so that the whole is cooled at the same instant.

Twist drills, taps, reamers, etc., are dipped vertically, and to move these sideways in the bath would distort them. To avoid this, the medium is stirred with a stick so as to give it a rotary motion, and the drill or tap is dipped in the centre of the swirling liquid, and moved vertically upwards and downwards. Blades for lawn mowers, shear blades, and similar things should be gripped in the centre with the tongs, dipped edgewise in the liquid, and moved edgewise through it, or the liquid itself may be agitated. Sometimes the blade is held between two pieces of iron slightly larger than the blade, and the whole dipped together. A hammer face, if dipped in the liquid, would cool at the edges before it did at the centre, and for this reason a sprayer or jet of water directed on the centre of the face is preferred.

Tempering.

May be accomplished by placing the cutter in a gas stove and raising the temperature to about 500° F., when the gas is shut off and the whole allowed to cool slowly.

Some prefer to first reduce the temperature of formed cutters to about 800° F. in the air blast, then to plunge the same in tallow at 200° F., when the temperature is again raised to about 500° F. and the whole allowed to cool.

Grinding.

The tool should be ground by *hand* pressure on a *wet* sandstone wheel. If it is necessary to use the emery wheel, the tool should be roughly ground to shape after forging, and finished on the wet sandstone after hardening.

Hardening High-Speed Steel Tools *

(1.)

The heat treatment usually prescribed for hardening high-speed steel tools consists in heating the nose of the tool slowly and uniformly to a red heat, then rapidly to a white or welding heat, at which the steel commences to fuse and blister, and then cooling either rapidly or slowly in air or quenching in oil.

The Department of Scientific and Industrial Research desires to direct the attention of users of high-speed steel tools to the fact that uniform and improved results may be obtained by carrying out the hardening process in two stages in accordance with the instructions given

* Communicated by the Department of Scientific and Industrial Research to the *Ministry of Munitions Journal*, and reproduced by permission of the Editor of that Journal.

below. This treatment is the outcome of the researches of F. W. Taylor in America, and of Carpenter, Edwards, Dempster Smith, and others, in this country. It may be stated that the adoption of this process for the hardening of special tools required for a most important purpose in connection with the war has yielded consistently uniform results, which are immensely better than the best results previously attained. The procedure given below is that adopted by Mr. Dempster Smith in the researches on tool steel carried out in the Manchester School of Technology for the Manchester Association of Engineers, with the aid of a grant from the Research Department.

First or High Heat Treatment.—Thoroughly preheat the tool to about 800° C. (1,472° F.), and transfer immediately to a high temperature furnace at a temperature of not less than 1,350° C. (2,462° F.) for ordinary high-speed tools, and about 1,320° C. (2,408° F.) for super high-speed steel. Retain it in the furnace until the surface of the tool nose is covered with small blisters slightly larger in size than a pin's head, in the case of ordinary high-speed steel, or until the entire surface of the nose is in a state of incipient fusion, or in the case of super high-speed steel presents a greasy appearance. The steel in the first case will have attained a temperature of about 1,320° C. (2,408° F.), and in the second a temperature of 1,290° C. (2,354° F.). Remove the tool and cool in an air blast of large volume.

Second or Low Heat Treatment.—Reheat the tool hardened as above to 570° C. (1,058° F.), for half an hour for tools with sections of half an inch square, or longer in the case of larger sections, and cool in an air blast or in still air. If carefully handled a higher temperature of about 610° C. (1,130° F.) may be adopted if the treatment is limited to ten minutes for tools of the smaller section, and slightly lower for those of larger section. All temperatures for the first and second heat treatment should be measured by means of a pyrometer, and care should be taken to ensure that the portion of the tool under treatment is uniformly heated throughout to the required temperature.

(2.)

The prevailing method of heating tools in ordinary gas furnaces, even when the utmost care is exercised, does not yield uniform results as regards cutting efficiency. The following procedure will be found to yield uniform results :—

First or High Heating.—The preliminary heating to about 800° C. (1,472° F.) may be carried out in a gas-fired muffle or semi-muffle. Care should be taken at this stage to ensure that the whole of the nose of the tool or the part to be heated subsequently to a high temperature is brought uniformly to the required temperature. The high heating to 1,350° C. (2,462° F.) should be carried out in a gas-fired furnace with a reducing flame so disposed that the heating of the tool is effected more by radiation from the heated surfaces of the furnace than by contact with the gases. It is important that the tool shall not be brought directly in contact with the burning gases. Detailed drawings of a furnace to fulfil the above conditions will be furnished on application to the Department.

Second or Low Heating.—This may be carried out at 570° C. (1,058° F.) in a gas-fired muffle or in a lead bath.

Tool Steels.

The treatment given above may be applied to steels containing tungsten, chromium, or vanadium, and generally to ordinary brands of high-speed tool steel. It may be found that certain special steels require a modification of the above treatment, particularly of the temperature required for the second heating; in such cases users are advised to refer to the makers of the steel, or, if possible, to investigate the matter for themselves.

Results.

When the heat treatment described above is carefully carried out, it will be found that the cutting efficiency of the tools is high and is maintained throughout the entire length of the nose, and that no further heat treatment is necessary after grinding (see page 984). The second heat treatment toughens the steel, and its advantage is very pronounced when working tools at high speeds.

Furnace.

A type of gas muffle recommended is illustrated on page 987, fig. 55.

Oil Fuel Heating Systems.

(Abstract of paper read before the Royal Society of Arts by Mr. A. F. Baillie.

Billet-heating furnaces using the air-jet system, with air and oil preheated by the exhaust gases showed a consumption of 9 lbs. of oil per 100 lbs. of metal heated for drop stamping. In

heating furnaces for nut-making, the consumption was found to be about 4 lbs. of oil per 100 lbs. of metal heated, and for bolt-making about 4½ lbs. A test on a bolt-making furnace 9 ins. by 12 ins. by 20 ins. resulted in 400 to 500 gross of bolts of from ⅜ in. to 1 in. per week on a consumption of 300 gallons of oil. Rivet-heating tests show for some furnaces on this work a consumption of 10·3 lbs. of oil per 100 lbs. of metal heated. For pot furnace work a tilting crucible furnace takes about 10 lbs. of oil per 100 lbs. of gunmetal melted, an open-hearth furnace about 11·8 lbs., and a lift-out furnace about 12·5 lbs. of oil. Stock converter furnaces for melting cast iron and steel-making take about 15 lbs. of oil per 100 lbs. of metal for melting only, but the total, including lighting and heating up, runs to about 40 lbs. In glass works the tank type of furnace takes about 37 lbs. per 100 lbs. of finished glass. An Italian plant of open-hearth Siemens basic furnaces of 55 tons capacity, with an output of 150 tons of steel per 24 hours per furnace, the oil consumption ranges from 16·5 tons to 18·75 tons, or from 11 lbs. to 12·5 lbs. per 100 lbs. metal. The air pressure for atomisation was 4 kilos. per sq centimetre.

The Burdon Oil-Gas System.

In this system the oil fuel, first very finely atomised and intimately mixed with a large volume of air at *low pressure*, is converted into gas in a small retort, and from the retort the gas is delivered into the furnace (through pipes of varying diameters), where, by the regulation of the air supply, any desired flame can be obtained. The intimate mixture of gas and air produces very high heating results, the full calorific value of the fuel being obtained.

The temperature is regulated by adjusting the valves which control the oil and air supplies.

By proper regulation of the air the fuel burns with a non-luminous Bunsen flame, and complete combustion with entire absence of smoke is easily secured.

The air and fuel can be supplied in any proportion desired, so that the flame in the furnace may be either reducing, oxidising, or neutral as desired.

A furnace 10 feet by 6 feet can be brought from cold to approximately 3,000° F. in less than three hours.

The Burdon system can be used for billet heating, slab and bloom heating, chain making, all kinds of welding and forging, case-hardening, tube heating, rivet and bolt making and heating, tin smelting, tool heating, horseshoe making, etc., also for steam raising, superheating, glass melting, metal melting, assaying, insulator making, etc.

Later developments effected in this system enable any quality of liquid fuel, either heavy crude fuel oil, or such as a mixture of 50 per cent. pitch and 50 per cent. of a tar-oil, or, alternatively, any of the lighter fuel oils, such as creosote and gas oils, etc., to be used with results giving high heating efficiency and economy in oil fuel.

The furnaces, which are made in various sizes, from small portable rivet heaters up to large forging types, consist of a combined generator and heating chamber. The oil is contained in the tank, from which it flows, without pressure, to the atomiser and the hot carburettor, where it is vaporised and intimately mixed with the air supply, forming a combustible gas, which passes to the actual heating chamber. The waste gases from this chamber pass through flues to the upper chamber to maintain a sufficient heat in the carburettor, to gasify the oil fuel.

Among the advantages claimed for this system are:

Cleanliness of installation and economy of space.

The producers can be applied to existing furnaces with a minimum of alteration or reconstruction.

Remarkably small fuel consumption, and no coal or coke trimming, stoking, or removal of clinker or ashes.

The cost and time of working is less than for coal or coal gas-fired furnaces.

Compressed Gas System.

There is an optimum pressure for the various applications of gas, and in order to meet this the gas can first be compressed to (say) 280 inches head of water (about 10 lbs. per sq. inch) which can be controlled at the various furnaces, etc., to the pressure required at each place. Pressures for typical work are as follows:—For melting tin or solder 65 inches; small hardening furnaces 65 inches; for blueing steel 65 to 80 inches; for the steel tempering lead pot 150 inches; while for melting metals at 2,000° F. to 2,600° F. 200 inches should be used.

Soldering irons can be heated at 65 inches pressure, which pressure is also convenient for the lighting.

With gas at 2*s*. per 1,000 and coal at 20*s*. per ton, there is little to choose between gas and coal firing as regards fuel costs. As regards cleanliness, uniformity, wear and tear of pots, and accuracy of control, the advantages are however in favour of gas, and in many cases with properly

GAS MUFFLE FURNACE FOR HEATING HIGH-SPEED TOOLS.

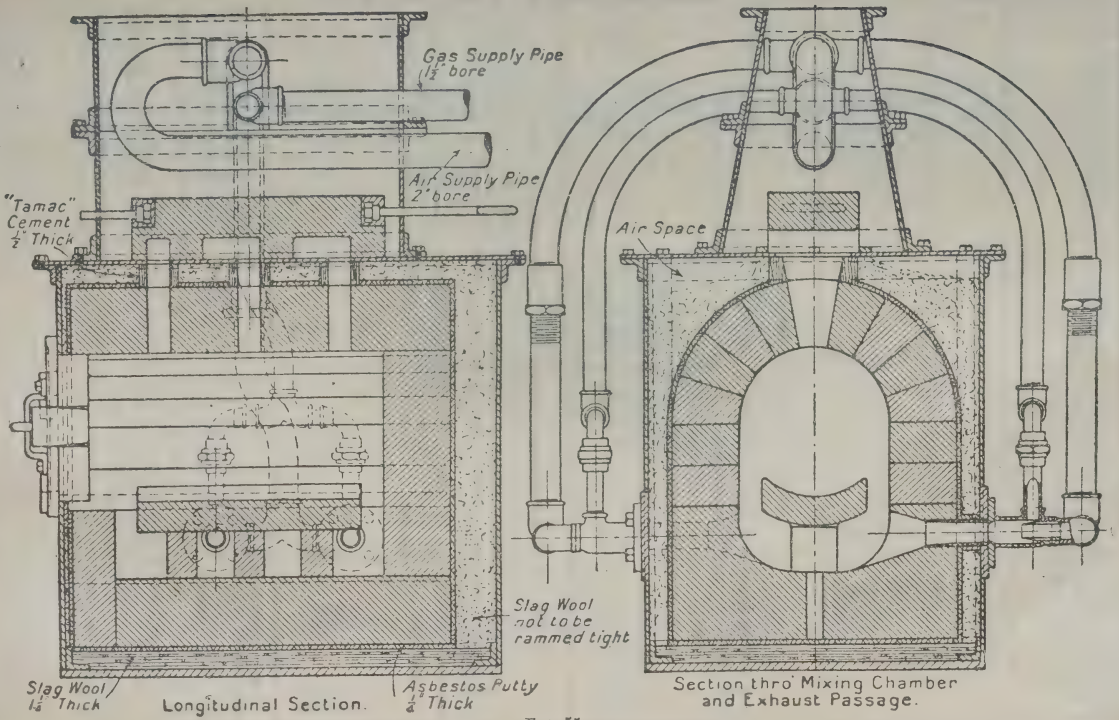

FIG. 55.

designed furnaces it is greatly superior to coal, not only from the point of view of cost, but from convenience, reliability, and ease of manipulation. There is also a large saving of time taken and space occupied by a gas furnace as compared with a coal furnace of similar power, factors of great importance when increased output is called for.

Low-pressure gas with air blast is largely adopted.

TABLE OF COMPRESSOR DATA.

Capacity of Compressor. Cub. ft.	H.P. required.	Floor Space. Ins.

Colours of Tempered Steel.

The *tempering* in this case relates to lowering the degree of hardness obtained by plunging the steel when heated to a cherry red (1,650° F., 899° C.) in cold water :—

Colour.	F.°	C.°	Colour.	F.°	C.°
Very pale yellow	430	221·1	Dark purple	550	287·8
Straw yellow	460	237·8	Clear blue	570	298·9
Brown yellow	500	260·0	Pale blue	610	321·1
Bright purple	530	276·7	Blue tinged with green	630	332·2

Composition of Quenching Baths for Tempering Cutting Tools.

Fused nitrates of potassium and of sodium are too high in temperature for certain cutting tools, as they do not permit of cooling below 328° F. (220° C.). Mixtures of nitrate of potassium and of nitrate of sodium can, however, be employed, and a series of mixtures, fusing at different temperatures, be obtained.

Temperature.		Nitrate of Potassium.	Nitrate of Sodium.	Temperatures.		Nitrate of Potassium.	Nitrate of Sodium.
F.°	C.°			F.°	C.°		
536	280	0 parts	100 parts	279	137	55 parts	45 parts
446	230	20 „	80 „	293	145	60 „	40 „
342	172	40 „	60 „	437	225	80 „	20 „
293	145	50 „	50 „	635	335	100 „	0 „

Higher temperatures than 752° F. (400° C.) cannot be obtained with these mixtures. In steels where without extreme hardness absolute absence of brittleness is necessary, 932° F. (500° C.) to 1,112° F. (600° C.) are temperatures more suitable. The following bath gives, on fusion, a temperature of 932° F. (500° C.) :—

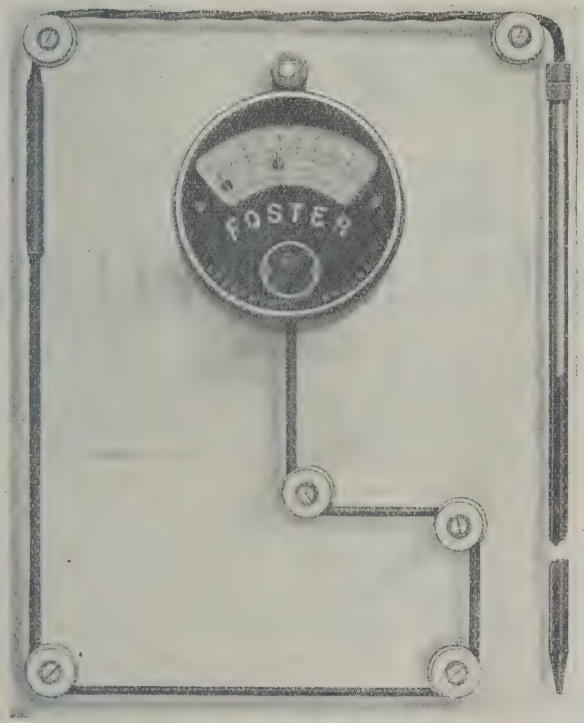
Sodium chloride, 1 part; potassium chloride, 1 part; fused calcium chloride, 2 parts; hydrated barium chloride, 1 part; hydrate strontium chloride, 3 parts.

For a bath fusing at 1,292° F. (700° C.) the following mixture may be used :—

Hydrated boric acid crystals, 1 part; silver sand, 1½ part; anhydrous potassium carbonate, 1 part; anhydrous sodium carbonate, 1 part.

When prolonged treatment is required, a little cyanide or charcoal may be added to prevent superficial decarburisation; but, in view of the strongly cementating action of cyanide, this salt must be used with caution.

QUENCHING LIQUIDS.



When hot steel is continually dumped into a tank of oil, the lighter and volatile oils are evaporated and finally only the heavier oils will be left. When the oil becomes thick, it will not take the heat away from the steel rapidly; consequently, the steel will be soft and will not

how the maximum physical properties. To obtain good results, the quenching liquid should be of a constant specific gravity and maintained at a temperature of 70° to 90°, but the exact temperature at which the bath is maintained does not matter so much if it is always the same. To ensure the best results, the bath should always be maintained at a certain specific gravity and at some certain temperature. (*'Machinery,' New York.*)

Grinding.

1. The tool should be forged roughly to shape and ground to the requisite contour by means of a composition wheel (preferably dry) without any lubricant being applied. The heating of the tool during grinding at this stage is not of any importance.

2. After shaping, the tool should be subjected to the two heat treatments indicated (page 984).

3. It is advisable to finish-grind with a copious stream of water playing on the nose of the tool. If reasonable care to avoid heating be exercised, the tool may be ground on a composition wheel running in water.

In hardening and tempering a chisel, the best way, says the *English Mechanic*, is to heat it to a very dull red for a good inch up from the edge, holding the tongs in the left hand, and in the right a rub stone, a piece of broken grindstone or emery wheel, or, failing these, a piece of emery cloth wrapped round a small file. Dip the chisel for about half-an-inch until it just turns black, then withdraw it from the water and let it rest against the side of the pail, so as to steady it; rub it sharply with the stone, so as to brighten it, and watch the colour as it runs down from the part which is still hot, and when the edge is of a deep plum colour, verging on blue, dip it right out.

Shape of Tool for Roughing Purposes.

The durability or length of time a tool will continue to cut under constant conditions as to feed, speed, etc., increases with the nose radius (fig. 56). The tendency to chatter, however, limits

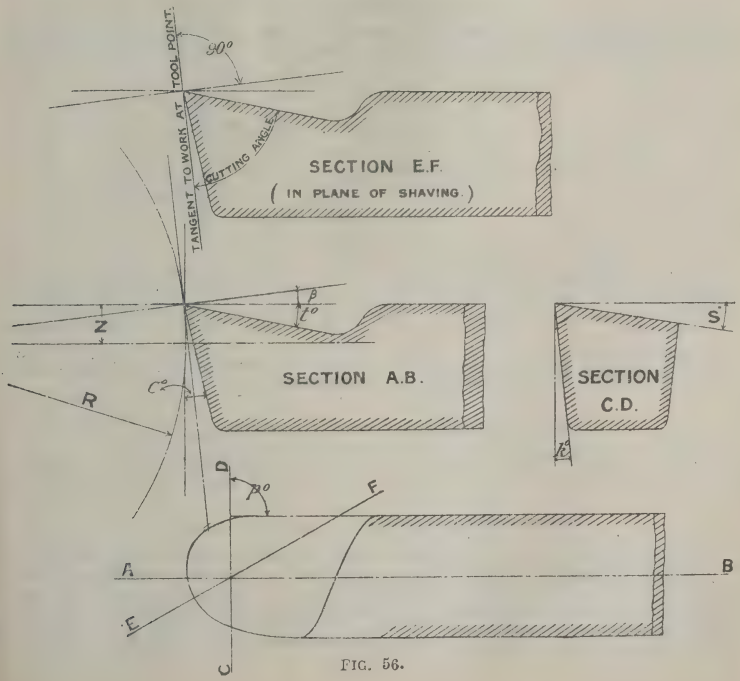

FIG. 56.

the extent to which the nose radius may be increased, and a round-nosed tool having a radius of $\frac{1}{8}$ in. to $\frac{1}{4}$ in. has been found to give the most satisfactory results for the general run of work. With work of a springy character a smaller nose radius may be required. The durability is also affected by the cutting angle, i.e., the angle between the cutting face of the tool and the tangent to the work or 90° minus the top rake angle. The cutting angle is increased when the tool edge stands above the centre of the work, by an amount equal to the angle contained between the cutting edge of the tool and the axis of the bar.

The cutting angles which give the greatest durability to tools for roughing purposes are as follows:

Material.	Cutting Angle.	Material.	Cutting Angle.
Soft steel	65°	Soft cast iron	70°
Medium steel	70°	Medium cast iron	75°
Hard steel	80°	Hard Cast Iron	85°
Nickel steel	80°	Brass	85°
Manganese steel	85°	Hard gunmetal	85°

The above angles are measured in a plane at 45° to the length of the tool which is approximately the plane of the shaving. The side and front clearance angles for tools with cutting edges on the line of centres need not exceed 6°. The shape of the tool recommended is shown below.

Front top rake ($t°$); height above centre (Z); front top rake (reduced to centre) ($\beta + t°$); side top rake (S°); front clearance ($C°$); radius of work (R); angle (β); front clearance reduced to centre) ($C°-\beta$); side clearance ($k°$).

Steel Tool Shanks.

By the ordinary method of welding, or securing by other means, high-speed steel tips to ordinary steel tool shanks, the shank is weakened considerably at the point where the high-

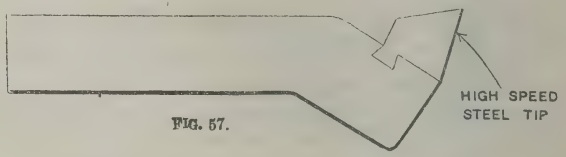

FIG. 57.

speed tip is applied, owing to the shank being cut away to accommodate the steel tip. In the J.B.R. system (the *J.B.R. Tool Co., Ltd., Longsight, Manchester*), fig 57, the shank retains its original strength, the steel tip being held in a dovetail slot and brazed in position by a method which renders the two materials, when heat-treated, absolutely homogeneous at the joint.

The tools, which are stocked in a range of thirty-nine different shapes, each shape being manufactured in four sizes and two heights, are being largely used.

Sharpening-angles of Wood Machine Cutters.

Adzing soft wood across the grain, 30°; planing machines, ordinary soft wood, 30°; gouging and ploughing machines, 30° to 35°; hard-wood tool-cutters, 35° to 40°.

Cutting Speeds for Carbon Steel Lathe Tools.

The following table gives the appropriate cutting speeds for different depths of cuts and traverses when roughing out with carbon steel tools of the lathe type, having a nose radius $\frac{1}{8}$ in., on various metals. When finishing soft, medium, and hard steel the cutting speeds which may be used are 20 ft., 15·5 ft., and 11 ft. per minute, whilst for finishing soft, medium, and hard cast iron the cutting speeds are 24 ft., 19 ft., and 14 ft. per minute in the order given. When finishing brass and copper, speeds of 80 ft. and 150 ft. per minute respectively should be adopted. The finishing cut should not exceed $\frac{1}{32}$ in. in any case. (*Dempster Smith.*)

TABLE OF CUTTING SPEEDS IN FEET PER MINUTE FOR CARBON STEEL LATHE TOOLS.

For ordinary Mushet steel the above speeds may be increased from 33 per cent. in the case of the lighter cuts to 50 per cent. for the heavy cuts.

The following table gives the revolutions per minute for different cutting speeds and diameters of work or cutters:—

RELATION BETWEEN REVOLUTIONS, CUTTING SPEEDS AND DIAMETERS OF WORK.

Cutting Speed in Ft. per Min.	Diameter of Work or Cutter, in Inches.																	
	½	⅝	¾	⅞	⅞	⅞	1	1⅛	1¼	1½	1¾	2	2½	3	3½	4	5	6

CUTTING WITH ORDINARY AND HIGH-SPEED STEEL.

Steel.

Trials showed that 20 ft. per minute with a cut of $\frac{1}{16}$ in. by $\frac{1}{16}$ in. is the superior limit of speed for ordinary water-hardened steel operating upon Whitworth fluid-compressed soft steel;

whilst an ordinary Mushet tool can run at over 30 ft. per minute, with a $\frac{3}{16}$ in. by $\frac{1}{16}$ in. cut upon the same material.

Cast Iron.

The trials on *medium cast iron* showed that 25 ft. per minute is too high a speed with $\frac{3}{16}$ in. by $\frac{3}{16}$ in. cuts; 17 ft. is too high with $\frac{3}{16}$ by $\frac{1}{16}$ in. cuts; and 15 ft. is too high with $\frac{3}{16}$ in. by $\frac{1}{8}$ in. cuts for ordinary water-hardened tool steels. An ordinary Mushet ran for over 20 minutes at 23·6 ft. per minute on a $\frac{1}{16}$ in. by $\frac{1}{16}$ in. cut; whilst it failed at 19 ft. per minute on a $\frac{5}{16}$ in. by $\frac{1}{16}$ in. cut, and at 15 ft. per minute on a $\frac{5}{16}$ in. by $\frac{1}{4}$ in. cut on this material.

In the case of *soft cast iron*, 22 ft. per minute was too high a speed for water-hardened steel taking a $\frac{5}{16}$ in. cut by $\frac{1}{8}$ in. traverse; whilst an ordinary Mushet lasted over half an hour at 31·6 ft. per minute with the same cut upon the same material.

Heavy cuts are much more economical in power, for the waste work is a much larger proportion of the whole work required at light cuts than at heavy cuts. It is probably this fact which has given rise to the commonly accepted opinion that the cutting stress increases with the speed (as instanced by the objections of workmen to increase cutting speeds on account of the anticipated springing of the work), contrary to the results of these trials, which rather show the reverse to be the case. In soft steel, for example, the average horse-power required for actual cutting at $\frac{1}{4}$ in. by $\frac{1}{16}$ in. was 3, while at $\frac{3}{8}$ in. by $\frac{1}{8}$ in. it was 15. The friction horse-power of lathe and counter-shaft was about $2\frac{1}{2}$ h.p. The weight removed was about 105 lbs. and 445 lbs. per hour at the light and heavy cuts respectively, so that the weight removed per gross h.p. hour was 19·1 lbs. for the light and 25·3 lbs. for the heavy cut. Neglecting frictional loss, these figures would have been 35 and 29 respectively.

In the case of cast iron, the gain in power at the heavier cuts is still more conspicuous. Here the effective h.p. was 1·7 and 5·5 at the $\frac{1}{4}$ by $\frac{1}{16}$ and $\frac{3}{8}$ by $\frac{1}{8}$ cuts respectively, the waste h.p. being about 2. The weights removed were 42 lbs. and 198 lbs. per hour, and the weights per h.p. hour were therefore: 11·35 lbs. at the light cut, and 26·5 lbs. at the heavy cut.

These results show that more material can be removed in a given time with a heavy cut at its proper speed than with a light cut at the highest speed which the new steels can take, and that this can be done at a smaller expenditure of gross power per ton of shavings removed.

VARIATION OF CUTTING FORCE WITH AREA OF CUT, AND OF CUTTING STRESS OBTAINED IN THE ABOVE TRIALS.

For steel the cutting force is simply proportional to the area of cut, and this force has the following approximate values in tons per sq. in.:—

For soft steel (fluid compressed)	. 115	For soft cast iron	51
„ medium steel „ „	. 108	„ medium iron	84
„ hard steel „ „	. 150	„ hard iron . . .	82

Fine traverses take more power than coarse ones.

Cutting stress does not vary much with speed, but tends to diminish.

Special high-speed tool steels will cut twice as fast as ordinary Mushet steel, and more than four times as fast as ordinary water-hardened steel.

(*Proc. Manchester Assoc. of Engrs.* 1903.)

Cutting Lubricants.

The mineral oils best suited for use as cutting lubricants, either alone or mixed with animal or vegetable oil, are preferably of pale colour and low viscosity, ranging from 100 to 200 seconds Redwood at 100 deg. F., those of lower viscosity being used for high-speed conditions and those of higher viscosity for slow speeds. Tinged lard oil, containing as much as 10 or 15 per cent. of free fatty acid, is the animal oil most frequently used, either alone or in admixture; prime lard oil, which is almost free from acid, is more expensive, but is less inclined to gum under severe conditions of heavy cut and high speed. Wherever possible a mixture of lard oil and low cold test mineral oil is to be preferred on account of greater fluidity in the cold. Cottonseed oil oxidises more readily than rape oil, and should not be used for cutting lubricants that are to be employed in a circulation system.

Good cutting oils used straight will not cause rusting, but those containing fixed (animal or vegetable) oils, such as lard oil with a large percentage of free fatty acid, will give rise to verdigris on brass. Vegetable oils such as rape, with a small percentage of free acid, do not produce verdigris unless they are rancid. Cutting emulsions made up from cutting compounds or soluble oils and water cause rusting if they are used too weak or if they contain acid. Water containing sodium chloride is most destructive to emulsions and must not be used, nor must hard water on account of the precipitate caused by the calcium and magnesium salts in it. Emulsions of oil and water are not stable in the presence of even minute quantities of acid; to a limited extent they can be reformed by neutralising the acid with ammonia, but excess of alkali may facilitate corrosion.

Factors in Selection.

Low speeds and shallow cuts require little cooling and lubrication. Low speeds and heavy cuts demand a lubricant of great oiliness, particularly if the material is tough. High speeds and shallow cuts demand a cutting medium with great cooling properties; hence emulsions are favoured and should be used if the speeds are particularly high. Turpentine substitute is a satisfactory lubricant for aluminium, but being inflammable must be used with care. A mixture of paraffin oil and lard or other cutting oil for high speed work on aluminium is also dangerous and has led to several fires. Cutting emulsions which possess the necessary cooling properties, and are not inflammable, are to be preferred. High speeds and heavy cuts demand a cutting lubricant with great cooling and lubricating properties; hence heavily compounded cutting lubricants of low viscosity must be used. For tough material and heavy cuts an emulsion containing 15 to 20 per cent. of a vegetable oil has been reported to be satisfactory.

Cutting emulsions are nearly always used for brittle material, and frequently for tough material if the speeds are high and the cuts light; when the material is tough and the cut heavy it is necessary to employ cutting lubricants used straight and containing 10 to 50 per cent. of animal or vegetable oils, or consisting entirely of such oils. Emulsions, in some cases, have been found to form a deposit on the working parts of automatic screw-cutting machines; this may be avoided by using straight oils, but emulsions should be adopted wherever possible in view of the present scarcity of oil. The amount of soluble oil or soluble compound used in preparing the cutting emulsion varies from 2½ to 20 per cent.; the richer mixtures are used for severe conditions, and the weaker for light duty or for materials like brass and aluminium, where there is no danger of rusting.

The cutting lubricant may be applied by hand by a drop-feed system, or by some system employing gravity or pumping. In large machine shops the cutting oil is sometimes circulated in pipes throughout the works, returning through other pipes to a central tank; group systems with central tanks are excellent where one mixture is used for all the machines on the circuit. The return pipes should be large and arranged for easy access for cleaning; isolating valves should be employed to sectionalise the system when large; efficient strainers should be fitted on all return pipes and pump sections, and should be cleaned daily. Tanks, as a rule, should be cleaned out every four weeks, and return pipes every four months. Any scum formed should be skimmed off the tanks daily. It must be remembered that the oil or emulsion, in any system in which it is circulated over and over again, is exposed to the admixture of dust and dirt from the machine shop and to the oxidising influence of air. The suction of any pumps that are employed should always be covered to prevent air from being drawn in, since aeration of the oil or emulsion has a strong oxidising effect upon it.

In machining aluminium (drilling, planing, etc.), use a lubricant of lard oil, kerosene, or a mixture of kerosene and gasolene or lard oil, for free cutting and a good finish.

Effects on Health.

Workers should be instructed not to wipe their hands on rags before washing and to avoid washing their hands in the cutting compounds. Ether soap, which dissolves oil, has been found useful in preventing inflammation of the hair follicles, and dusting the arms with a powder containing equal parts of starch and zinc oxide before starting work prevents the action of the oil on the skin.

Workers whose hands have become the seat of septic infection should not be allowed to work on machines, as they are liable to infect the oil with germs and so infect others. As a general rule frequent washing with soap and hot water is sufficient to bring about rapid cure of folliculitis produced by plugging of the glands. Subsequently the skin may be dusted with zinc oxide and starch powder, and where this has been insufficient a mild antiseptic applied on lint has relieved the irritation and given good results. Septic infection of the skin due to cuts should be treated on general principles with suitable antiseptic dressings.

PORTABLE PNEUMATIC TOOLS.

The Boyer Long-Stroke Hammer.

This (fig. 58, p. 995) is one of the best and most generally used of all pneumatic riveting hammers at the present time. It has one distributing valve, which is placed at the rear end of the cylinder. The air-ports in the valve and cylinder of this hammer are so designed that the full air pressure is available to drive the piston forward on its working stroke, but the ports in valve and cylinder provided for effecting the return or idle stroke of the piston are of small area, so that the pressure used for this work is considerably reduced by wire-drawing, and the piston is returned practically without shock to the operator. The vibration of these hammers is thus reduced to a minimum.

For holding up against the riveting hammer, any of the present hand methods may be employed, and quite good work can be done either with the old-fashioned mawl, or a plain dolly bar consisting of a piece of wrought iron weighing about 28 lbs. Where a suitable backing can be

THE BOYER LONG-STROKE RIVETING HAMMER.

FIG. 58.

THE NEW GIANT DRILL.
(*The Consolidated Pneumatic Tool Co. Ltd.*)
FIG. 59.

found for it, the pneumatic piston holder-on is most useful, and for boiler work and in certain classes of heavy shipyard riveting the hammer type of holder-on is frequently used. This gives a series of blows on the head of the rivet whilst it is being formed.

Pneumatic riveting hammers are now recognised as thoroughly practical and efficient tools for dealing with any class of work which was formerly done by hand, and rivets from ¼ in. up to 1½ in. diameter can be closed by suitable tools. It takes from 7 to 10 seconds to close a ¾ in. snap-headed rivet.

The air consumption of these tools is generally 25 cubic feet of free air per minute, and the pressure may be from 80 to 100 lbs. per square inch, the latter figure being necessary for the heaviest class of riveting, and particularly for steam- or water-tight work.

Caulking Hammers.

The chipping or caulking hammer has now taken its place as an indispensable every-day tool, without which present rates of output could not be maintained. The average chipping hammer will remove mild steel at the rate of 3½ to 4 oz. per minute, and the air consumption is from 17 to 20 cubic feet of free air per minute: pressure from 80 to 100 lbs. per square inch.

Drills.

A pneumatic drill of average size can be relied upon to drill in mild steel plate 1 in. diameter holes at the rate of 1 in. to 1½ in. deep per minute, and larger and smaller holes in proportion, the air consumption varying from 30 cubic feet in the average drills to 50–60 in the larger tools. Usual air pressure 80 lbs. per square inch. Reamering and tapping are also among the varied uses to which these tools can profitably be put. Pneumatic drills are now available in a large range of sizes, from a tool weighing 8 lbs. for drilling $\frac{3}{16}$ in. holes up to a weight of 85 lbs. and a capacity for 3 in. drilling and tapping. (See fig. 59, page 995.)

Pneumatic Tools for Salvage Work.

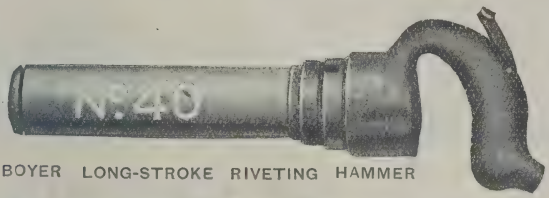
The chipping hammer and drill mentioned above can be fitted for use under water, for ship repairs, dock construction, and other similar work, and are already very largely used in this connection.

Air Mains and Receivers.

Air Mains for the distribution of compressed air are generally made of wrought-iron piping of steam quality, and should be so arranged that the rate of flow will not very much exceed 50 feet per second. At intervals along this main, or wherever tools are likely to be employed, a tee piece should be inserted which will take a connection for the flexible rubber hose which joins up to the tools. An important point to take care of is the provision of adequate means for draining any moisture from the air receiver or the pipe lines themselves, and it is advisable to arrange for the discharge of the compressor to deliver the air at the top of the receiver, and to connect the air main lower down. This assists in depositing any moisture which may be in the air as delivered from the compressor.

Air Receivers should be fitted with a manhole, in order that their interior condition may be examined from time to time, as it is possible for corrosion to take place, or on the other hand, if the lubrication of the compressor is not carefully attended to, a large deposit of oil will be formed, which may result in an explosive mixture being present in the receiver.

Tubing and Tube Couplings.



Flexible Metallic Tubing (*The United Flexible Metallic Tubing Co. Ltd.*, 112 *Queen Victoria Street, London*) is being largely used for pneumatic tools. As the tubing withstands crushing and cannot kink, it is well adapted for conveying compressed air to pneumatic drillers and other machines.

Belliss & Morcom Pneumatic Hose Coupling.

This coupling (fig. 60) which is simple in construction and convenient in use, does not rely on springs to maintain its lock, being immediately sealed by the internal pressure, and cannot unlock of its own accord in or out of use. It is claimed to be absolutely air-tight; easily and quickly disconnected; practically unbreakable, being made from steel bar; dust-proof, and being gun-blacked, will not easily rust. Having no external projections, it can be easily drawn through close quarters or past work lying about the shop.

The rubber jointing being held securely in place, cannot blow out, but can be easily removed by hand for replacement when required.

It is screwed on the shank and tapered to facilitate fitting on the hose. The ends of each hose pipe can be locked together, thus giving a neat appearance when coiled up. Additional hose for extensions can be connected up instantly. The coupling is supplied in the following sizes:—½ in. gas for chipping hammers, drills, riddles, etc.; ¾ in. gas for riveting hammers, etc.; 2 in. gas for coal-cutting tools and pressure mains.

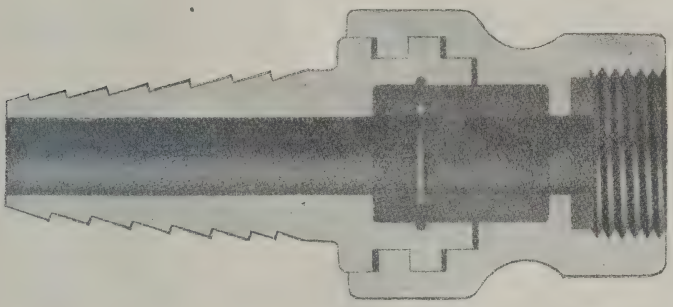

FIG. 60.

CARE OF PNEUMATIC TOOLS.

Unless pneumatic tools are kept clean, well lubricated, and limited to the uses for which they are intended, they will not give the service for which they are designed. Wherever possible, the air supply should be drawn from some point outside the building where the air is most apt to be clean, cool and dry. In any event, a strainer should be placed over the exposed end of the inlet pipe. Such a strainer can be easily made by covering the opening with wire netting over which one or two layers of muslin have been placed. A strainer should also be placed in the pipe lines leading directly to the pneumatic tools, and a strainer inserted between the pneumatic hammers and the hose nipple.

Lubrication.—Valves and pistons for both hammers and drills require a light machine oil, and as the compressed air which comes in direct contact with these parts has a tendency to drive the lubricant out through the exhaust, it is advisable to oil such parts freely and often, about once every hour while the tool is in constant use. Such portions of the tools as the gear and crank cases to which the compressed air does not have direct access are best lubricated with grease. This grease may be forced into the crank cases through the dead air handle by means of a squirt gun or syringe. A filling every 10 hours while the drills are in constant use gives the best results. It is a good plan to immerse pneumatic hammers in a bath of benzene or kerosene over-night and then blow them out under pressure the following morning, after which they should be thoroughly lubricated with a light machine oil.

Pneumatic Riveting.

According to information received from one of the leading East Coast shipyards, the best day's work on a shell with pneumatic riveting is 700 rivets of ⅞ of an inch diameter, and for hand work, under the same conditions, 430. An average day's work, however, is considerably less than this, and may be taken as being 510 rivets with pneumatic rivets, against 264 with a hand squad, the figures being taken for work on all parts of one ship. According to the *Board of Trade Journal* the following may be taken as indicating the difference in the day's work of a hand and pneumatic riveting squad:—On the shell, with ⅞ in. rivets, hand-riveting, 260 to 360 rivets; with pneumatic riveting, 500 to 550; on the deck, with ⅝ in. rivets, hand-riveting 450, pneumatic 700; on deck with ¾ in. and ⅞ in. rivets, hand-riveting 350, pneumatic 550. Again, the pneumatic tool requires fewer men to work it. A hand-riveting squad consists of three men and one or two boys. From two of these squads three pneumatic riveting squads can be formed, effecting a saving of 50 per cent. in labour alone. A third advantage of the pneumatic tool is that it gives both the other great advantages with less exertion and consequently less fatigue on the part of the men. (*Machinery.*)

Files.

DESCRIPTION.

Single-cut.		*Double-cut.*		*Rasp.*	
Rough	Second-cut	Coarse	Smooth	Coarse	Second-cut
Coarse	Smooth	Bastard	Dead-smooth	Bastard	Smooth
Bastard		Second-cut			

The terms 'rough,' 'coarse,' 'bastard,' 'second-cut,' 'smooth,' and 'dead-smooth,' have reference only to the coarseness of the teeth, while the terms 'single-cut,' 'double-cut,' and 'rasp' have special reference to the character of the teeth.

RE-SHARPENING FILES.

The sand-blast process consists of injecting fine sand against the backs of the teeth by means of a steam jet, and is applicable to all files, from the rasp to the finest Groubet files. The action of the sand is to cut away the backs of the file teeth, thus forming a straight level on the teeth back, and giving a new cutting edge, and the process occupies from 3 to 5 minutes.

Another method is first to carefully cleanse the files with hot water and soda; they are then brought into connection with the positive pole of a battery, in a bath composed of 40 parts sulphuric acid and 1,000 parts water. The negative (zinc) pole of the battery is connected to a copper spiral surrounding the files but not touching them. This arrangement is the result of practical experience. When the files have been in the bath for 10 minutes they are taken out, washed, and dried, when the whole of the hollows will be found to have been attacked in a sensible manner; but should the effect not be sufficient, the files are replaced in the bath for the same period as before. Sometimes two operations are necessary, but seldom more. The files thus treated are to all appearance like new ones, and are good for 60 hours' work.

Tube Cutters.

WINN'S STRAIGHT-CUT ROLLER TUBE CUTTER.

The particular feature in this cutter, fig. 61 (*Charles Winn & Co., Birmingham*), consists in widely separated duplex rollers, arranged in a block on the spindle end, making it practically impossible

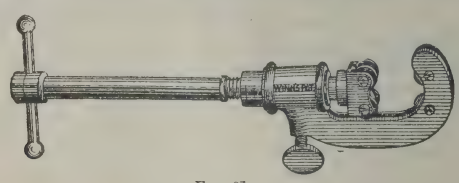

FIG. 61.

to set the tube cutter on the tube operated upon in any other way than absolutely at a right angle with it. All who have had occasion to cut a tube will realise the important gain this means, because no time is lost in cutting screw tracks on the tube, and there is no consequent breakage of cutters. The rollers save all friction on the tube, and two cutters are provided in the hook so that tubes can be cut off with great ease and speed. There is a further saving of time by the use of this tool, in the quick adjustment for different sizes ($\frac{1}{4}$ in. to $1\frac{1}{2}$ in. for one tool). The hook is of best malleable iron, and all other parts are of steel—the screw works in a long steel nut, and the rollers are hardened to prevent wear.

Cold Chisels.

A large number of the chisels now in use are not forged, shaped, and hardened in the best way to give long life and adequate service. Considering the making of a chisel from $\frac{3}{4}$ in. octagon tool steel, the following method has been found to give good results:—

Forging.—Cut off a length of steel, depending on the length of chisel desired, and heat up the end for 2 ins. to a bright cherry-red. Trim off two opposite sides so as to form a blunt-nosed

tool and eliminate the danger of lapping when drawing out. The horn of the anvil should be used in drawing out, inasmuch as this will have the least possible tendency to widen the piece, and therefore the minimum amount of 'edging-in' or hammering on the edge will be necessary. A chisel should not be hammered on the edge, because the grain of the steel will thereby be distorted or 'crumpled up,' and this always has a tendency to weaken any metal. If in the final forging operation the chisel gets a little too wide, it can be trimmed off on the emery-wheel during the grinding operation.

Draw the chisel out so that it will be about $\frac{1}{8}$ in. thick at the end and about $\frac{3}{8}$ in. thick and $1\frac{1}{4}$ in. back from the end. The forging should be finished with light blows until the steel has almost lost colour, but it absolutely must not be struck after the colour has disappeared. It is good practice to reheat the steel to a dull red without using any blast, and give it a second hammering with light blows until the colour has again almost disappeared.

The four important things to remember in forging a chisel are, therefore: Draw out at a

FIG. 62.

FIG. 63.

FIG. 64.

good cherry-red heat; finish with light blows at a dull-red heat; do not hammer after the colour has disappeared; hammer as little as possible on the edge, and then only when the steel is fairly hot.

Grinding.—Grind the chisel before it is hardened, as it can be ground faster in this way without the danger of drawing the temper. The shape of the edge of the chisel is very important, although this fact is often overlooked. Fig. 62 shows a chisel ground with a concave edge. If this is driven down on to a flat surface, it is obvious that a great strain will be put on the corners, and they are almost sure to break off. Fig. 63 shows a chisel ground with a perfectly flat edge. If this chisel is driven down on to a flat surface and held perfectly straight the cutting strain will be distributed evenly over the entire edge, and the chisel will be satisfactory. It must be remembered, however, that it is almost impossible to hold a chisel absolutely straight, and, therefore, either one corner or the other will be severely stressed by the chisel being tilted over. Fig. 64 shows a chisel ground with a slightly convex edge, which is by far the best for ordinary work. The corners of a chisel are always the danger point, and with the convex edge these corners are protected even when the chisel is tilted over considerably to one side or the other.

Hardening and Tempering.—After the chisel has been ground to the desired shape, heat it to a dull cherry-red colour for about $2\frac{1}{2}$ ins. from the end, and quench it vertically in cold water to a depth of $1\frac{1}{2}$ ins., moving it up and down until no red colour is left in any part of the steel. The part which has been drawn out should now be polished with emery cloth and the temper drawn to a dark purple or a blue by holding the chisel over the fire or in a furnace. Always draw a chisel a little more in winter than in summer. It has been recommended to harden the chisel back much farther than usual, because a chisel so made can be ground a great many times without redressing. (*Joseph T. Ryerson and Son, Chicago.*)

To Reduce the Internal Diameter of a Steel Bush.

A bush was required to be a force fit on a 6-in. shaft; and should have been bored 5·999 ins. ± 0·002 in., but was bored 0·015 too large.

The bush was heated to just a red, about 2 ins. up, at one end, and just 1 in. of the 2 ins. dipped in cold water. It was next heated another inch or two up, keeping the first cooled inch as cool as possible, and then dipped a further inch into water. This was continued inch by inch, each cooled inch apparently pulling in the inch in the length adjacent to it until the whole of the bush (or sleeve) was pulled in quite twenty thousandths, and required to be skimmed out 0·005 in. to force it on to its shaft. (*J. T. T.*, '*Machinery.*')

Gripping Pieces of Uneven Width in the Machine Vice.

If two or more pieces have to be held in the machine vice for drilling or other operation, and their widths differ slightly, a strip of lead, *s*, placed as shown in fig. 65 will compensate for the

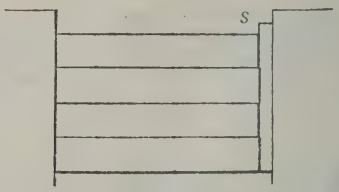

Fig. 65.

irregularity and afford a secure grip. Or a piece of belting, cloth, canvas, wire meshing, etc., will serve the purpose.

Hardness of Materials.

Different Methods of Determining Hardness.

The test to which a material is generally subjected in order to obtain a measure of its hardness may be of two classes, viz. :—

(1) The resistance offered by the material under investigation, (2) the resistance offered by the material to abrasion or cutting.

Of these, the first finds most extensive favour in practice, and the indenting medium may be a chisel, cone, or sphere. Repeated use on hard materials is inclined to blunt the chisel edge or point of the cone, and the sphere is the agent commonly adopted.

In 1900 Brinell introduced a method of ascertaining the hardness of a material by indenting it with a hardened steel sphere subjected to a predetermined load. The ratio of the load on the sphere to the area of indentation produced gives the hardness figure. The ball commonly used is 10 mm. diameter. The load for the softer materials is usually 500 kilograms, and that for the harder metals 3,000 kilograms.

The load should be applied for at least 30 seconds in order to secure equilibrium between it and the resistance of the material. The diameter of indentation is observed by means of a special microscope fitted with a scale, and from this the depth of indentation can be calculated, since :—

$$\triangle = \tfrac{1}{2}\left(D - \sqrt{D^2 - d^2}\right),$$

where $\triangle$ is the depth of indentation,
d „ diameter „
D „ „ of the sphere.

The hardness figure or number N for a load P is given by the expression :—

$$N = \frac{P}{\frac{\pi}{2} D \left(D - \sqrt{D^2 - d^2}\right)} = \frac{P}{\pi D \triangle}.$$

The hardness number is therefore inversely proportional to the diameter of ball and depth of indentation, and for a ball of constant diameter is directly proportional to the load. The hardness numbers for diameters of impressions made by a ball 10 mm. diameter under a load of 3,000 kilograms are given in the table, page 1002.

The depth of indentation may be obtained directly by means of a micrometer microscope by observing the difference between the readings of the datum line on the piston when the parts

are brought together and after the load has been applied and removed. This procedure precludes the possibility of including the compression of the piston, sphere, and other parts of the machine beyond the datum line.

As it is difficult to bring the parts together without indenting the specimen to some extent, a small initial load may be applied. Observations of the datum line are then made when the initial load is applied, and also after the full load has been applied, and when the load has been brought back again to its initial value.

By measuring the actual depth of penetration, the error due to the elastic deformation of the sphere (which is included when the diameter is observed) is avoided. This elastic deformation is relatively greatest when the load, and consequently the indentation, is least. As the indentation increases so does the lateral component of the resisting force, and this tends to keep the sphere to its true form.

In testing some cast irons the metal flows from beneath the ball and causes a ridge to be formed which stands proud of the original surface, whilst with bronze and, some of the copper alloys the metal is drawn in. In the case of the former the diameter observed is greater than the true value corresponding to the depth of indentation, whilst in the latter case the diameter is less than its true value.

The Shore Scleroscope.

This instrument consists of a small hammer, weighing about $\frac{1}{2}$ of an ounce and fitted with a diamond which is somewhat spherical in shape at the striking end. The hammer is suspended on a stirrup piece fitted to a head on a vertical stand, and upon which is also mounted a glass tube about 10 inches long and a graduated scale subdivided into 140 parts. The hammer is released and raised by a pneumatic device and moves within the tube. As the end of the glass tube is made to rest upon the material under investigation, the hammer always falls through a definite height and the measure of hardness is obtained by observing its rebound on the scale. The hammer on striking makes a permanent impression in the material, but as this is very small and irregular in outline it is impossible to measure the depth or diameter with any approach to accuracy.

The hammer is liable to become blunt with use, and a block of hardened steel, having a 100 hardness, is furnished for calibrating purposes.

Abrasion Test.

An early conception was to scratch a smooth surface of the material under investigation with a sharp point of a mineral, a number of minerals being selected to constitute a scale of hardness. In their order of hardness these were :—(1) talc, (2) gypsum, (3) calcite, (4) fluor, (5) apatite, (6) felspar, (7) quartz, (8) topaz, (9) sapphire, (10) diamond. The method is only suitable for materials which differ widely in hardness.

To obtain a measure of hardness of materials which differed but slightly, Professor Turner developed the *Sclerometer*. This instrument consists of a diamond carried at one end of a balance lever in a horizontal plane and which rested upon a knife edge fitted into a vertical pillar. The pillar was free to turn by hand, so that the diamond was made to travel across the smooth face of the metal being investigated. The end of the lever carrying the diamond was loaded and the weight in grams necessary to produce a scratch of standard depth gave a measure of the hardness.

With apparatus similar to the above some have taken the width of the scratch produced by a diamond under a constant load as the measure of hardness. As the scratch is very minute it has to be measured by means of a microscope and the surface must be smooth and polished, in order to give a sharp definition. The test is therefore more adaptable to the laboratory than to the workshop.

Drilling Test.

This test can be made with an ordinary sensitive drilling machine having a vertically free spindle. A constant load is applied to the spindle, so that the drill is made to penetrate the material under observation. The revolutions made in drilling a hole of predetermined depth gives a measure of the hardness or tenacity.

With the object of observing the variation in the hardness as the drill proceeds, the machine is fitted with a drum which rotates with the descent of the spindle. A screw, attached to the drum support, carries a nut in which is fixed a pencil. The screw is driven from the spindle, and as the nut cannot rotate the pencil moves in the plane parallel to the drum axis. The combined motion caused a diagonal line to be traced on a piece of paper around the drum, the height and horizontal length of the line being proportional to the depth drilled and revolutions respectively. The slope of the line varies with the hardness, and a soft or hard patch in the material under test is shown on the graph by the line becoming steeper or flatter in the order mentioned at that part. The drill is periodically tested for sharpness on a piece of material of standard hardness. (*Dempster Smith.*)

GRINDING, ABRASIVES, AND POLISHING APPLIANCES.

ABRASIVE MATERIALS — NATURAL GRINDSTONES — ABRASIVE WHEELS AND BLOCKS — LUBRICATION — DRY VERSUS WET GRINDING — SELECTION OF WHEELS — SPEEDS OF WHEELS — MOUNTING ABRASIVE WHEELS — GRINDING MACHINES — WHEEL GUARDS — GRINDING PROCEDURE — CYLINDRICAL GRINDING — EXTERNAL GRINDING — CENTRELESS GRINDING — INTERNAL GRINDING — SURFACE GRINDING — GRINDING ALLOWANCES — POLISHING — SAND BLASTING.

Revised and amplified by Alfred B. Searle
(Consulting Advisor on Abrasive Materials.)

GRINDING, ABRASIVES, AND POLISHING APPLIANCES.

The appliances used for grinding and polishing may be divided into two chief groups :—

(*a*) The *abrasive materials*, which may be in the form of powders, liquids, wheels, blocks cups, etc.

(*b*) The *machines* used in the application of such materials, and commonly known as 'Grinding and Polishing Machines.'

Abrasive Materials.

The chief *natural* abrasive and polishing materials are sandstone, sand, emery, corundum, diamond dust, pumice, rotten stone, tripoli powder, rouge, lime, whiting, and chalk. The chief *artificial* abrasives are : (i) carbon silicide, which is known by various trade names, such as carborundum ; and (ii) fused or crystalline alumina or artificial corundum, which is also known under a variety of trade names.

These materials are ground and then sifted so as to ensure the particles being of sizes suitable to the particular purpose for which they are to be used ; this being a matter of great importance.

These abrasive materials may be used in the form of powders, or suspended in water, oil, or other convenient liquids (as liquid polishes), or they may be made into grindstones, wheels, blocks, etc.

Natural Grindstones.

Natural grindstones are made by cutting blocks of suitable stone to the desired size and shape. The stones used for this purpose are shown by the following table :—

FOR GRINDING MACHINISTS' TOOLS.

Name of Stone.	Kind of Grit.	Texture of Stone.	Colour of Stone.
Nova Scotia	All kinds, from finest to coarsest	All kinds, from hardest to softest	Blue, or yellowish-grey
Bay Chaleur (New Brunswick)	Medium to finest	Soft and sharp	Uniformly light blue
Liverpool or Meling	Medium to fine	Soft, with sharp grit	Reddish

For Wood-working Tools.

Name of Stone.	Kind of Grit.	Texture of Stone.	Colour of Stone.
Wickerolz	Medium to fine	Very soft	Greyish-yellow
Liverpool or Meling	Medium to fine	Soft, with sharp grit	Reddish
Bay Chaleur (New Brunswick)	Medium to finest	Soft and sharp	Uniformly light blue
Huron, Michigan	Fine	Soft and sharp	Uniformly light blue

For Grinding Broad Surfaces, as Saws or Iron Plates.

Name of Stone.	Kind of Grit.	Texture of Stone.	Colour of Stone.
Newcastle	Coarse to medium	Hard	Yellow
Independence	Coarse	Hard to medium	Greyish white
Massillon	Coarse	Hard to medium	Yellowish white

Maximum Speed of Natural Grindstones.

Except under expert advice, grindstones should not be run at a higher peripheral speed than 3,400 ft. per min. This corresponds to the following speeds of rotation:—

Diameter of Stone.	Revolutions per Minute.	Diameter of Stone.	Revolutions per Minute.	Diameter of Stone.	Revolutions per Minute.
Ft. Ins.		Ft. Ins.		Ft. Ins.	
8 0	135	6 0	180	4 0	270
7 6	144	5 6	196	3 6	308
7 0	154	5 0	216	3 0	360
6 6	166	4 6	240		

Abrasive Wheels and Blocks.

Grindstones which are made from abrasive powders are commonly known as 'Abrasive Wheels,' and as these were first made of emery, such wheels are still sometimes termed 'Emery Wheels,' even when made of other materials!

The manufacture of vitrified abrasive wheels and 'artificial' grinding wheels is really a branch of the clayworking industry, as the particles of abrasive material are held together by clay or by a mixture of materials in which clay is an important ingredient, the wheels being moulded from a plastic state and afterwards burned in kilns at a temperature of about 1,400° C. The details of the manufacture of these wheels are kept secret. In other abrasive wheels, the binding materials are shellac, rubber or silicate of soda.

Abrasive wheels, blocks, etc., are classified according to the nature of the abrasive (corundum, carborundum, emery, etc.), the size of the abrasive particles and the hardness or tenacity of the bond.

Whatever the nature of the work may be, if it has hitherto been done by means of files, much greater economy, speed, and quality can be obtained by using such wheels in their place, especially when the wheels are used on the varied machines to which they are applied. The great profit to be derived from the general introduction of abrasive wheels is due to saving in wages, files, increased output, and improved work.

It should no longer be assumed that a grinding wheel cannot remove metal and shape work as quickly as a steel tool, but the latter should be used when it can do the work more cheaply, and the grinding wheel when it excels. Poor wheels, or good wheels wrongly used, will still remove metal slowly, but a modern grinding wheel used in a modern machine is a milling cutter just as truly as if made of steel, and is to be regarded as a cutter with millions of teeth, which, while they may not cut so deeply, can cut more rapidly—as, for example, at speeds of 6,000 or more surface feet per minute. Cams and crankshafts can be produced more cheaply by grinding than by turning. With automatic grinders it is possible to turn out work even more rapidly. Where 300 pieces per day were ground by piecework, 2,300 are now produced. As the knowledge of grinding becomes more common, and the opposition on the part of workmen to increased production is overcome, the field for grinding will be still more extended.

(*C. H. Norton before Amer. Soc. of Mech. Engrs.*)

The *grade* of a wheel is represented by a letter, being the hardest and the softest. The term 'grade' is confined to the relative hardness of the wheel or block as a whole, and does not refer to the hardness of the abrasive particles. This distinction is important, because the cutting or abrasive power depends quite as much on the bonding material as on the abrasive particles.

No wholly satisfactory method of grading abrasive wheels, etc., has yet been devised, various mechanical devices of testing having proved unsatisfactory. The method adopted by manufacturers consists in gouging the wheel with a tool resembling a screw-driver, the 'feel' indicating the grade with fair accuracy to an experienced tester. It is, however, almost impossible to compare accurately the grades of abrasive wheels made with different bonds, as they do not work equally satisfactorily with any material.

The term '*grit*' is used to indicate the sizes of the abrasive particles present, and it is usually expressed by figures indicating the number of meshes per linear inch in a sieve through which the abrasive particles will pass completely. Thus, in a 60-grit wheel or block the abrasive particles will pass completely through a sieve having 60 holes per linear inch. It should be observed that the grit only indicates the largest particles, and has no reference to their average diameter nor to the proportion of much smaller particles present. It is understood, however, that there is only a small proportion of particles sufficiently fine to pass through a sieve which is represented by the next grit figure.

GRIT SIZES OF GRINDING WHEELS.

The *suitability* of an abrasive wheel or block for any given purpose depends on the grade or hardness of the wheel as a whole, on the grit or size of the abrasive particles, and on the *bond* which unites them together.

For grinding steels and the harder materials, i.e. materials with a high tensile strength, wheels or blocks composed of an aluminous abrasive (corundum emery) are preferable. For cast iron, chilled iron, brass, soft bronzes, aluminium, copper, granite, marble, leather, wood, and other materials of lower tensile strength, wheels or blocks composed of a carbide abrasive (carborundum, cristolon, etc.) should be used. The binding agent which unites the particles of abrasive also determines the suitability of the wheel or block for any given purpose. Thus—

(i.) Rubber-bonded abrasives are very tough and resistant, and so are specially suitable where a bond of exceptional strength is required in conjunction with a thin wheel or ring, as in the case with various cutting operations, such as slotting iron plates, sawing stone, cutting glass and saw teeth, or sharpening milling cutters of awkward shape, as well as for cutting metals, grinding chilled iron rolls, and for other work where a fine finish is required. Shellac-bonded wheels are too soft for this purpose. They are also used where it is necessary that the shape of the abrasive article should be retained as long as possible. This is particularly the case with the thin cutting discs used by watchmakers, dentists, etc.

(ii.) Shellac-bonded wheels are used for cutter and reamer grinding, pointing drills, sharpening knives, saws, and other edge tools, and for similar purposes as rubber-bonded wheels, but as they are more elastic they can be used to give a finer finish. They will not stand high temperatures, but can be used for wet or dry grinding. They are less porous and less free cutting than wheels with a vitrified bond. They are singularly free from 'glazing,' as the baked shellac has lost the stickiness characteristic of the natural material.

(iii.) Silicate wheels are very close in texture, and as they cut freely they are very useful for grinding tools and cutlery.

(iv.) Abrasive articles made with a vitrified bond are characterised by a high porosity, a great resistance to heat and acids, and great freedom in cutting. They may be used for almost any purpose if care is taken to select them of suitable grit and grade, though when very thin cutting wheels are required it is often preferable to use a shellac—or rubber-bond may be preferable. If too much bond is present the abrasive articles tend to 'glaze' badly, owing to the bond not falling away with sufficient rapidity from the cutting points. With too little bond, on the contrary, the articles will be weak and, in the case of wheels, cylinders, or rotating rings, they may be dangerous on account of their liability to break when in use.

Lubrication.

The rate, effect, and efficiency of the grinding are also affected by the water or other lubricant applied to the wheel when in use. The function of the water is to carry away the heat resulting from the friction between the abrasive and the article being ground, and to wash away any loose particles dislodged by the grinding.

The water supply for all external grinding operations should be ample in volume without force. Using, say, a 14-in. diameter wheel, not less than 5 gallons and up to 10 gallons per minute should be used; on larger wheels 20 to 50 gallons per minute.

For many purposes, solutions of soap or emulsions of oil and water are preferable to plain water. A solution of carbonate of soda containing 2 oz. per gallon has the advantage of not producing rust, especially if $\frac{1}{4}$ or $\frac{1}{2}$ pint of lard oil is mixed with it.

In grinding aluminium it is advisable to use a lubricant of lard, oil, kerosene, or a mixture of kerosene and gasolene or lard, or oil and gasolene.

Dry *versus* Wet Grinding.

In certain circumstances water may—or must—be dispensed with. Whenever it is necessary to see the edge of the wheel distinctly, to be sure of reaching some particular spot, water cannot be used, as it obstructs the view. Work revolving in the chuck or on the faceplate is also generally ground dry, as water is awkward to deal with on ordinary machines under such conditions. Cutters are also usually ground dry, although special care has to be taken to prevent 'drawing the temper' of the cutting edges. The amount to be removed is, in most cases, small, so that the sacrifice of time is balanced by the greater convenience of dry grinding.

More material can be ground away by dry internal grinding than by wet, and it is fairly common practice to run water on the work externally to dissipate as much heat as possible whilst grinding dry internally. On such classes of work as aeroplane cylinder grinding, or ring gauges where a high degree of accuracy and finish is essential, water must be used, but it should be in such volume as to prevent as far as possible the chips being carried round to the wheel and interfering with the cut.

In *wet grinding*, care should be taken that the water supply is steady and adequate, and particular attention must be paid to this in the case of tool grinders, where it is of the utmost importance that the tool should be effectively covered with water, to obviate any loss of temper in the steel during the process of grinding. Some grinding machines provide for this; e.g. in one such patent machine the water is forced by a centrifugal pump through a series of small holes in the tool rest itself, in such a manner as to completely envelop the tool being ground. A noticeable feature of this grinder is that there is total absence of splashing.

In the

Selection of an Abrasive Wheel

the most important points to be kept in mind are *suitability for the particular class of work*, and *safety from accident*.

It is obvious to everyone that a wheel specially manufactured for fettling iron castings is not the one to be used for needle pointing, but few people, except those connected with the trade, have any conception of the number of kinds or classes into which such wheels have been divided and subdivided, each main group (designated by symbols, B, S, SS, G, R, M, etc.) being varied in hundreds of ways to suit the work.

The general practice is to state the purpose for which the wheels are required and leave the selection to the judgment of the makers; it is to their interest to give satisfaction. The other particulars to be given when ordering are—quantity required, diameter, thickness, and size of centre hole.

Grindstones are softer when wet than dry, and should not be left partly immersed in water or they will wear unevenly. Stones made with sorel cement as a bond should not be used for wet grinding as the cement is disintegrated by water.

Speed of Wheels.

This varies somewhat according to the make, and the purpose for which they are used.

The peripheral speed of a grinding wheel—which is a function of its diameter and the number of revolutions per minute which the wheel makes—has a marked effect on the apparent hardness of the wheel. Hence, the hardness or grade of an abrasive wheel or cylinder appears to vary with the speed at which it rotates. Thus, by running a soft wheel above its normal speed it appears to become harder, and by reducing the speed of a hard wheel it appears to become softer. Hence, by varying the speed within reasonable limits a wheel which is normally too soft or too hard may be used satisfactorily.

As a wheel wears, its peripheral speed is reduced and the wheel appears to soften, but by increasing the number of revolutions per minute so that the original peripheral speed is obtained the wheel appears to regain its former hardness. Many workers suppose that the faster the work revolves the greater will be the output, and so they use very hard wheels which require maximum driving power and cause a maximum wear of the machine. Yet, in most cases, they produce work of inferior quality which requires a longer time and greater effort to produce than if softer wheels and slower work speeds were used.

The following speeds are typical, but should be modified to suit particular cases:—

Application.	*Peripheral Speed in Feet per Min.*
Cylindrical grinding	5,500 to 6,500
Snagging and general off-hand grinding on bench and floor stands	5,000 ,, 6,000
Surface grinding	4,000 ,, 5,000
Knife grinding	2,000 ,, 3,000
Hemming cylinders	2,100 ,, 2,400
Tool grinding	3,000 ,, 4,000 *
Vertical surface grinding machines	4,000 ,, 4,500
Elastic and rubber cut-off wheels	9,000 ,, 12,000
Polishing wheels	about 7,000

For speeds higher than the above, slightly softer grades should be used to off-set the harder cutting action; for lower speeds slightly harder grades than would be ordinarily supplied should be used.

For polishing purposes a much lower speed is desirable; thus, the cloth wheels known as 'mops' or 'dollys' used for buffing metals usually run 20 ft. per second.

It is impossible to state exactly the speed at which any article or part to be ground should rotate. It is largely a matter of experiment, as the speed should be suited to the abrasive and to the nature of the material to be ground. With Norton cylindrical grinders a peripheral work-speed of 60 to 80 ft. per minute is often used for roughing, and 30 to 40 ft. per minute for finishing. It is customary to rough-grind at a higher surface speed of work than on finish-grinding.

In grinding cylinders the speed at which the article to be ground rotates is of great importance, as by running the grinding wheels at a constant speed and varying the speed of rotation of the article to be ground it is easy to secure uniform results from wheels having a variation in speed of 2,000 ft. per minute, and a variation from true grade within practical wheel-making limits. Thus, by varying the speed of the article to be ground, the necessity for variable revolutions for the wheel, or close limits of speed and grade for the wheel, are made unnecessary, and variable speed for the work accomplishes all that variable wheel spindles can accomplish, and much more, in a more simple way, at less expense.

* Some large users of grinding wheels regard as maximum peripheral speeds for machinist's tools 800–1,000 ft. per min., and for carpenter's tools 550–600 ft. per min.

Mounting Abrasive Wheels.

If there is a large area of contact the method of mounting and safeguarding abrasive wheels and the condition of the grinding machine are of great importance. A grinding wheel should be fixed carefully and securely between recessed steel or iron plates or washers about half the diameter of the wheel, with a sheet of thin rubber insertion, or one or two thicknesses of brown paper, on each side between the wheel and the washer-plates (fig. 1).

The wheel should not project more than 2 ins. beyond the flanges. Both flanges should be

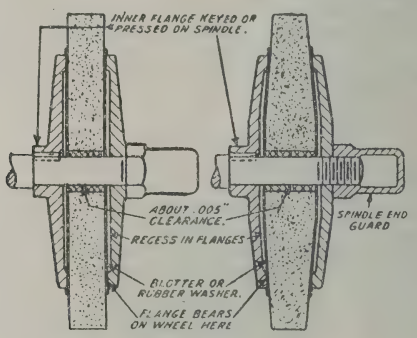

FIG. 1.

of equal diameter, to avoid cross-straining of the wheel. The inner flange should be keyed to the shaft and abutting against a shoulder on the same. Various firms have special mountings which have proved satisfactory.

The grinding wheel should never be mounted without washers. The hole in it should be slightly larger than the diameter of the spindle, as the wheel must not be driven tight on to the spindle. Care should be taken in screwing up very thin wheels that too much force is not applied. No wheel of more than 12 ins. diameter should be put on a spindle 1 in. thick, and other sizes in proportion.

Before using, the wheels should be trued up on their own spindles with a truing tool, and they should also be turned up when they get out of truth through wear. Grinding wheels, should revolve towards the rests, and the rests should be moved close to the wheels so as to prevent work being jammed between the rest and the wheel. The rest must never be moved while the wheel is in motion.

GRINDING MACHINES.

It is imperative that grinding machines be specially designed for the purpose intended, made of the best quality and workmanship, and that great care be taken in securing a suitable foundation as free from jar and shake as possible. The stands or bodies of the machines ought to be of a sufficient strength and massiveness to correspond with the size of wheel used. The same remark applies to the spindle, which must run in long and accurately bored bearings.

If the spindle is loose and cannot be put in good condition, a harder grade of wheel must be used than would ordinarily be recommended, so as to overcome the tendency to pound the wheel face to pieces. Light, flimsy machines, and those improperly secured to the foundation, also require harder grades than would ordinarily be used. Machines are frequently placed in the middle of a wooden floor which vibrates badly, and in this case harder wheels must be used than for a machine on a firm, solid foundation. A machine which is too light or imperfectly made is always a nuisance and is liable to prove very expensive. It is only too easy for good work to be spoiled by such machines, and they add unnecessarily to the cost of grinding, because they cannot be driven at the most appropriate speed for the work and because of various 'dodges' which must be used to obtain satisfactory results.

Rotary abrasive appliances may be mounted in a fixed frame—in which case the article to be ground, cut, or polished is moved gradually forward—or the work may be fixed and the abrasive mounted on a moving frame, so that it travels both forward and from side to side. There is an increasing feeling that this principle is wrong even in light machines; it is impracticable in heavy ones, where a wheel-head may weigh between 1 and 2 tons. When a heavy wheel is grinding to within $\frac{1}{1000}$th part of an inch, revolving at a speed of 6,000 ft. per minute at the

surface, and operating across a cutting face from 2 ins. to 4 ins. wide, it is clearly not a good mechanical proceeding to traverse such a mass under such conditions. The present practice, therefore, is to put plenty of mass into the wheel-head, and to support it rigidly directly from the floor. Then the only movement which it receives is that of feeding inwards to the work. Incidentally, also, the necessary travel of the table requires a long table, which, again, avoids excessive wear. A slow table or traverse speed should be used when taking heavy cuts, but for finishing a high traverse speed is preferable.

The belt-drives from cumbrous overhead shafts have disappeared from all except the smaller and medium-sized machines, as electric drives have largely displaced this clumsy method and permit overhead-travelling cranes, or overhead tracks, to have free range. The large cylindrical grinding machines of to-day, therefore, have no belt-drive from above. A motor is installed somewhere alongside the bed, and the grinding wheel is belt-driven from that; the work speeds and the wheel-feeds are changed through gears enclosed in boxes protected from grit. The convenience of this arrangement, which is only rendered possible by the electric drive, is inducing manufacturers to adopt similar arrangements for the smaller machines.

In the best machines no mild steel and cast iron is used for shafts and gears. High carbon or alloy steels alone are used for these. Nickel, nickel-chrome, or chrome-vanadium steels ensure strength and durability, without which the small shafts and gears of fine pitches would soon show serious wear. Friction is reduced by the universal fitting of ball-bearings for taking circular and end thrust. Lubrication is provided in various ways, ring-oiling to the main bearings, forced water-supply to the work and the wheel, and a large supply-tank or tanks with a circulating pump. New forms of steadies have been evolved, and more are used, besides which steadies for some duties are specially designed. The necessity for supporting work almost continuously receives more recognition than it formerly did, and the work is better supported on the bottom and in opposition to the wheel.

As good grinding machines are costly, concessions to the requirements of the smaller firms, in the form of various attachments, are inevitable, but the tendency is towards using plain grinding machines, each limited to one set of functions, every detail being considered and worked out for that duty alone.

Van Dorn Tool Post Grinder.

This machine, fig. 2 (made by the Van Dorn & Dutton Co., Cleveland, Ohio), is furnished with an internal attachment as shown. It may be used for internal and external grinding on the lathe, tool grinding on the milling machine, and surface grinding on the shaper or planer. The spindle makes 4,500 revolutions per minute, and the weight of the machine is about 24 lbs. These machines are extremely useful on a wide variety of work in all engineering shops.

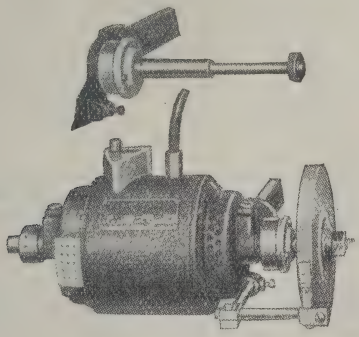

Fig. 2.

All parts of these machines are made accurately to gauge, ensuring perfect interchangeability. All adjustments may be easily made without removing any part of the machine. The taper bearing at the wheel end ensures the correct bearing adjustment being maintained. The bearing for taking the end thrust may be adjusted to exceptionally fine limits. The bearings are bronze and the lubricating system is very efficient. The motor is air cooled. The armature is form wound, a commutator of special design giving great rigidity and perfect insulation. The windings are insulated by a special process. The brushes are easily accessible. Adjustable rear handles are on hand types.

Bearings.—The design of the bearings is a special feature of Van Dorn grinders. The bearing for the wheel end is so constructed that adjustment for compressing the bearing can be effected in addition to expanding; thus a perfect running fit can be obtained, whilst efficient locking arrangements ensure that the adjustment cannot be disturbed.

Longitudinal adjustment is accomplished by means of a double thrust bearing provided with a dial cap. By depressing a locking pin the dial may be moved in either direction, enabling the adjustment to be made to within very fine limits.

Wheel Guards.

To meet the requirements of factory inspectors, a number of emery wheel guards, good, bad, and indifferent, have been introduced by manufacturers. The two features to be looked for in an appliance of this kind are:

(1) That it is of ample strength, and (2) that it can be readily adjusted to follow the wear of the wheel.

It is essential that the guard should be kept close to the periphery of the wheel in order to limit the flight of any portion which may break away.

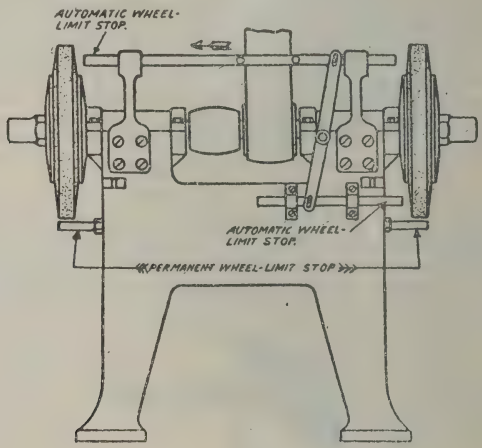

FIG. 3.

Machines fitted with two or more speeds should be provided with safety devices to prevent the maximum speed of the wheel being exceeded. In fig. 3 is shown a two-speed machine fitted with stops to limit the diameter and to prevent the belt being shifted to the high-speed pulley when the wheel exceeds a predetermined diameter.

The Safety of an Emery Wheel.

For safety, a protection hood made of rolled steel is preferred. The hood should cover as much of the wheel as possible and also the spindle end. The hood should be constructed to act as a dust hood which when connected with an exhaust system will eliminate the injurious effects of wheel dust. The wheel should be kept true and the work rest close to it.

Face or Cup Wheels ought to be protected by being well and properly secured inside a Safety Adjustable Chuck, designed to allow only a small portion of the wheel to project whilst at work, and constructed so as to secure and support the wheel as close to the grinding face as possible.

The modern grinding machine is practically a finishing machine in which the work produced needs no further correction. The sliding surfaces of the machine must be perfectly true planes, and there must be rigidity, particularly in the grinding-wheel head. It must be heavy enough to carry the largest and broadest wheels with which the machine may be possibly fitted, and also to overcome any possible want of balance in the wheel itself. The spindle and its bearings should be of ample proportions. The machine should be easily operated and controlled in its movements, so that a maximum amount of work can be obtained from it.

Grinding Procedure.*

Cylindrical Grinding—External.

The best average *surface speed* of modern grinding wheels, as made to-day from artificial abrasives, is about 6,000 ft. per minute for external cylindrical grinding, and the useful speed range is from 6,500 to 5,500 ft. per minute; below this speed excessive wheel wear is liable and very probable, and grinding machines should be arranged so that the effective life of the wheel falls within this range. It is of the utmost importance that the speed of the wheel be maintained during the cutting operation, no matter what the speed may be, and the drive should be sufficiently powerful to prevent slowing down during momentary heavy cutting. Not only is the wheel wasted by being allowed to slow down, but the wheel face is destroyed and more frequent truing up is necessary. It is more economical, from the point of view of wheel wear to metal removed, to keep the speed up so that softer and freer cutting wheels can be used, the speed enabling them to stand up to heavy cutting without undue wear, and, further, such wheels have very little tendency to glazing.

The *grade* of the wheel is determined by the material to be ground and the rigidity or otherwise of the work, and whether it is of large or small diameter. No definite rule can be laid down for the adoption of any particular grade, but it is unusual in general machine work to require more than two wheels to a machine, one to grind all classes of steel work and the other to deal with all cast metals. Closer grading can be done where the work is all of one class, as for instance, a machine may be employed wholly on cast-iron pistons, crankshafts, or piston-rods, etc., in which cases particular grades of wheels can be employed.

The *diameter* of the wheels should be as large as possible.

The direct result of using large diameter wheels is economy of operation, the cost of wheel per cubic inch of material removed being less than in the case of the smaller wheel.

The *wheel width* has a direct result on the output, providing it is made use of, and to utilise a wide wheel to its full extent the table-travel must correspond.

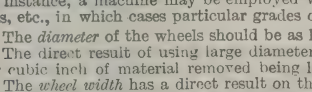

FIG. 4.—A = traverse per rev. of work = $\frac{3}{4}$ width of wheel. Maximum wear of wheel tends to concentrate on shaded portion.

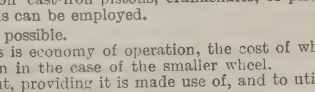

FIG. 5.—A = traverse per rev. of work = $\frac{1}{3}$ width of wheel. Maximum wear of wheel tends to concentrate on shaded portions.

Table Travel.—If the traverse of the work per revolution is less than half the width of the wheel, then the cutting face of the latter will gradually wear convex, but if the traverse per revolution of the work is over half the width of the wheel, then the wheel will preserve a flat face. (See figs. 4 and 5.)

The ideal traverse per revolution of the work is about two-thirds the width of the wheel, but it should not, except for finishing, be less than half the width.

The table should travel as rapidly as can be used. (See 'Cross-feed,' page 1012.)

The main factor governing production on external cylindrical grinding machines is the combination of wide wheels with fast table speeds, as, other things being equal, the machine which possesses these advantages is the most efficient tool.

The *work speed* has only an indirect effect on the output. With a good wheel it makes little difference to the finish obtained whether the work surface speed be, say, 30 or 60 ft. per minute, except that, if the lower speed is persisted in, it limits the table travel, and so in turn limits the output. For external cylindrical grinding the practice is to work on an average surface speed of 60 ft. per minute as a basis. Low work speed is directly conducive to distortion and inaccuracy. The heat created by the cutting action of the wheel must be dissipated or distributed as quickly as possible, and can only be done by a higher work speed and table travel aided by an ample flow of water.

Vibrations in the work itself and disintegration of the grinding wheel are more liable to occur in large diameter and heavy work than in small work. It is much easier to control vibration in small diameter work, and it would be almost impossible to rotate it at such a high speed as to disintegrate the surface of the wheel, but the tendency would be to cause unnecessary wheel wear, and if the table speed was such that the traverse was less than half the width of the wheel the latter would wear more at the corners than in the centre.

Vibrations on heavy work are much more difficult to control, and much depends on the

* Abstract of Paper read by H. H. Asbridge before the Manchester Association of Engineers.

machine and method of supporting the work. No definite rule can be laid down, as so much depends on circumstances. For instance, it would be both permissible and advisable to run an 8-in. tube at a higher surface speed than an 8-in. solid shaft, the limiting factor in the tube being a surface speed such as would cause disintegration of the wheel face, there being no heavy body of metal to set up vibration, whereas in the shaft the limiting factor would be a surface speed sufficient to set up an oscillatory motion difficult to control, and which would prevent the shaft from being ground to a perfect cylinder. This same defect could also be obtained by using a too slow surface speed, due to insufficient dissipation of the heat created by the grinding wheel. Between these two extremes there is a wide margin of surface speed at which grinding can be successfully carried on.

A good rule is to get a wheel suitably graded for the work, and when once a suitable grade is found it should be recorded, as wheels such as are made from artificial abrasives can be duplicated within very fine limits.

The *cross feed* to the grinding wheel should operate at each reversal of the table, that is, at the end of each stroke; this is necessary to distribute the work over the whole width of the grinding wheel. Production is not governed so much by the amount of cross feed as by other conditions. There should be as much cross feed as the work, the machine, or the grinding wheel will stand; this will be from ·0005 in. to ·0015 in. on the work diameter at each reversal of table. Under these conditions, a machine with a fast table travel will give maximum output with a comparatively light cross feed, as compared with a machine having only a slow table speed, and will have the advantage also of not stressing the work to the same extent. The wheel will remove more material for a given wheel wear, and the machine will be more economical in power.

Over-run of work should be avoided (see p. 1014).

The *time required* in external grinding cannot be calculated with any approach to accuracy on the usual basis of cutting speed and feed, etc.

The finish grinding of a shaft of a given diameter and length is not a constant operation with an abrupt termination, as in other methods of machining, but is an operation starting at zero, rising quickly to the point at which possibly the maximum cutting capacity of the wheel is demanded, and then falling gradually to zero or finished size, and the finer the limit fixed for the finished diameter, the more gradual will be the closing stages of the operation. Grinding times must, therefore, so far as the wheel is concerned, be based on a mean of its cutting capacity, much lower than its maximum.

The formula, as deduced from the above method, is as follows and is published for the first time:—

Diameter of work in inches × length in feet × constant = grinding time in minutes for the removal of $\frac{1}{32}$ in. in diameter and finishing to commercial limit.

TABLE OF CONSTANTS.

Diameter of Work.	Size of Wheel.	Constant.
4-in. shaft and upwards.	26 ins. by 3 ins.	1·3
3-in. ,,	,,	1·4
2-in. ,,	,,	1·8
1½-in. ,,	,,	2·2
1-in. ,,	,,	3
3-in. shaft and upwards.	14 ins. by 2 ins.	2·2
2-in. ,,	,,	3
1½-in. ,,	,,	3·7
1-in. ,,	,,	5
3-in. shaft and upwards.	12 ins. by 1 in.	3
2-in. ,,	,,	3·8
1½-in. ,,	,,	4·5
1-in. ,,	,,	6·3

For the removal of $\frac{1}{64}$ in. in diameter allow $\frac{2}{3}$ of time obtained. For work below 1 in. diameter the grinding time tends to increase, depending entirely on rigidity of support afforded to same. Extra time should be allowed to special limits, such as may be required for drive fits, etc., or for special finished surfaces, such as are necessary for spindles, gauges, etc.

CENTRELESS GRINDING.*

The objections to the use of centres to support the work during grinding, and the difficulty of accurately grinding gudgeon pins, crank pins, and other relatively long pieces of small diameter,

* Particulars supplied by S. W. Dowding & Co., 66 Victoria Street, S.W. 1.

can be avoided, and any irregularity caused by warpage in hardening removed by supporting the work in a suitable guide block. Two patterns (fig. 6) of guide blocks are used—one for rough grinding, and the other for finishing—the difference being in the relative positions of the three guide blades.

For rough grinding the near blade is adjusted so that the work projects beyond the lower front blade C, slightly more than the thickness of the material to be removed, whilst the upper blade, A, is given a clearance of 0·005–0·020 ins. In finishing, the upper and lower blades are more nearly vertical. The work is finished after it has been passed several times through the block.

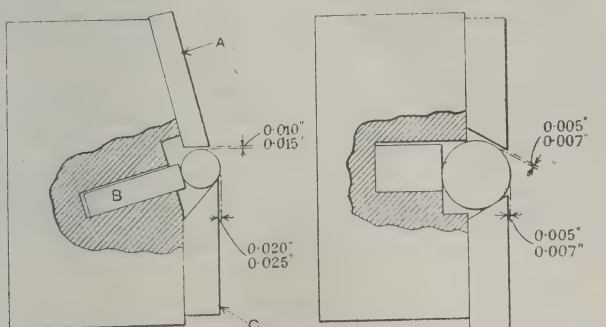

FIG. 6.

The face of the grinding wheel is conical, and is dressed to an included angle of 4–6 degrees, so that it has the effect of an increased surface speed as the work passes across the wheel face and compels the work to rotate slowly.

Lubrication and cooling of the work are essential.

The grinding is effected more rapidly than when centres are used.

INTERNAL GRINDING.

The idea that internal grinding cannot be satisfactorily accomplished at spindle speeds less than 30,000 to 50,000 r.p.m. is erroneous. Provided that there is rigidity in the spindle employed, the grinding-wheel diameter has little effect on production. The effective speed range of a good grinding wheel is very much greater than in any other form of grinding, and ranges from 1,000 to 4,000 ft. per minute, and much of the most successful grinding is done at the surface speed of from 1,500 to 2,500 ft., but a very rigid spindle is necessary.

There are two types of internal spindles, the ' tube ' type having a bearing immediately behind the wheel (this type is not to be recommended for holes, say, less than 6 ins. in length, as holes of this length, and longer, are generally insufficiently large in bore to admit of a substantial spindle), and the ' adaptor ' type. The construction of the latter type is such that the spindle bearings never enter the hole being ground, the wheel being carried on an adaptor fitted into the main spindle and held by a draw bolt, or, if the work to be ground is of limited range, the adaptor portion is formed integral with the main spindle. For general commercial work the loose adaptor is preferable, as long or short, heavy or light adaptors can be used suitable for the particular work in hand. The fact that the main spindle in this instance never enters the hole permits of it being made of liberal dimensions. The Churchill Machine Tool Co. fix the higher limit of such spindles at 1,500 r.p.m., and so long as the rigidity is there behind the adaptor no higher speed is necessary for holes from ½ in. upwards.

The *wheel width* has a direct result on the output.

Given a spindle with the necessary rigidity, the use of wide wheels and a high table speed are the governing factors in obtaining maximum production. The standard practice of the above firm is to use all wheels from ½ in. to 3 ins. diameter ¾ in. wide, above 3 ins. diameter 1 in. wide. Such wheels are of no advantage unless combined with high traverse speeds, in order to utilise as much of the wheel width as possible, and also to dissipate the heat generated evenly.

Table-traverse speeds up to 9 ft. and 10 ft. per min. are commonly applied to internal grinding machines.

The *work speed* in internal grinding can be varied considerably above or below the speed which has been previously determined to be the best for the particular work in hand. Such variation would have very little effect on production, but might affect the finish obtained. In standard practice a work surface speed of from 100 to 120 ft. per minute is used as a basis or starting-point, and varied according to circumstances.

The *cross-feed* requires special care in internal grinding.

Whatever type of internal grinding spindle is used (where the work to be ground is carried on a rotating spindle) there is bound to be overhang from its supporting bracket, with more or less unavoidable spring, and whilst the slide carrying the spindle can be set to a predetermined position with great accuracy, it does not follow that the hole being ground will have reached the desired size, owing to the spring in the spindle. This fact makes the use of automatic cross-feed almost impossible of accomplishment if the amount of the feed has to equal the amount of cut which the wheel will take at each traverse of the table. Hand-operated cross-feed fitted with an adjustment dead stop is therefore to be preferred.

In another type of internal grinding, the work is stationary and the grinding wheel has imparted to it a planetary motion whilst rotating at a high speed on its own axis, the planetary spindle being eccentrically adjustable whilst grinding is proceeding. This type of machine has been employed for grinding motor-car cylinders when cast *en bloc*, and the possibilities of this type of machine for finishing holes are great.

Over-run of work should be avoided; that is, the wheel should never be allowed to leave the work, the traverse being only just sufficient to allow of not more than one-third of the width of the wheel projecting beyond the end of the work. If the wheel is allowed to run off, the result in external grinding will be to have the face of the wheel sheared away by the sharp ends of the work; and in internal grinding the hole will be bell-mouthed.

SURFACE GRINDING.

There are two methods of surface grinding—one using the periphery of the grinding wheel, and the other the edge of the wheel. The wheel in the latter case is of cup form and carried on either a vertical or horizontal spindle, the more widely used being the vertical spindle type. The two methods are further subdivided according to the manner in which the work is moved, machines being made with the work carried on a reciprocating table, or on a circular revolving table, briefly classified as follows:—

1. Horizontal spindle surface grinding machine, where the work is reciprocated under the grinding wheel.

2. Horizontal spindle ring and surface grinding machine. In this machine the work is carried on a circular revolving table, generally made in the form of a magnetic chuck, and rotated under the grinding wheel.

3. Vertical spindle ring and surface grinding machine, where the grinding wheel is of cup form, carried on a vertical spindle, and the work is carried on a circular rotating table, generally in the form of a magnetic chuck and rotated under the wheel.

4. Vertical spindle surface grinding machine, where the wheel is of cup form carried on a vertical spindle, and the work is carried on a table reciprocating under the wheel.

The first and fourth types are the most commonly used, and intended for the grinding of flat surfaces of all kinds and in all materials.

The second and third types are widely used for grinding the sides of disc work, such as circular knives and saws, piston rings, disc valves, etc., using the rotary table. The second type of machine with the horizontal spindle leaves the work with a concentric finish, whereas the third type of machine with the cup wheel leaves the work with a radial finish, and which in some classes of work is objectionable, particularly, for instance, in piston rings, where the concentric finish is preferred. So far as production is concerned the vertical spindle ring and surface grinding machine will give a greater output than the horizontal spindle ring and surface grinding machine. Both machines can be arranged to grind flat, concave, or convex surfaces.

The most largely used machine for regular commercial purposes is the machine with the vertical spindle, owing to its greater productive capacity.

The best *wheel speed* for all-round surface grinding is about 4,000 ft. per minute, with very little margin of speed—that is, if a wheel is working successfully at 4,000 ft. per minute, it cannot be varied up or down from this speed without affecting production, consequently the vertical spindle machine with the cup wheel has a great advantage in this respect, due, of course, to the wheel retaining its diameter as it wears.

The grade of the wheel for surface grinding demands far closer attention than in any other type of grinding. The only remedy for a wheel that is too hard or too soft is to change it for a wheel of the correct grade.

A high *table speed* is the main factor governing output, using suitable grinding wheels, but the machine which will so work that the temperature is even throughout the whole ground surface will produce the most accurate results.

The vertical surface grinding machine with the cup wheel, which covers the full width of work at each stroke of the table, has a distinct advantage over the horizontal spindle machine using the periphery of the wheel, and which would have to be traversed transversely in order to cover a work surface wider than the width of wheel.

Quite apart, however, from the question of heat distribution, the vertical spindle machine has the greater productive capacity, and for grinding wide surfaces or groups of small articles this type of machine has the advantage of the horizontal spindle machine. The vertical surface grinding machine is now being adopted in all classes of engineering works, and wherever flat surfaces have to be produced, such as in machine-tool work, there is no method that can be compared with it for cheapness of production.

A machine of this type added to the equipment of any works, and used for the production of flat surfaces, has, more than any other type of grinding machine, a beneficial effect throughout the works, and in this respect raises automatically the standard of work produced. In this way, given an accurate machine, it is so very easy to true up straight edges and similar tools and keep them all in a constant high state of perfection; and by having a machine of this type always in readiness to produce flat surfaces the result is that more accurate work is automatically produced throughout the works.

The *time required* for grinding a given surface can be ascertained with fair accuracy once a basis is found, based on area ground and amount of metal removed. Under normal working conditions, a grinding wheel has a certain capacity for the removal of metal, based on its cutting area or its diameter and width.

Examples of Grinding.

The following examples will serve to show what may be expected from wheels which are suited to the conditions and work in hand :—

A batch of 72 soft steel spindles of diameters ranging from 1½ inch down to $\frac{9}{16}$ inch by 8 inches long, and having from ·010 to ·015 inch left for grinding, were finished in an average time of 4½ minutes each. The wheel was Norton 'Alundum' 60.M, running at a speed of 6,500 ft. per minute, and it lost ·0005 inch diameter for every six spindles ground. The work speed was 30 ft. for $\frac{9}{16}$ diameter, and 60 ft. for 1½ inch diameter, and the grinding limit was ·00025 inch.

Cast-iron spindle tubes 2½ inches diameter by 12 inches long took an average time of 10 minutes each to finish. The grinding limit was ·00025 inch, and the amount removed ·010 to ·015 inch. The wheel was Norton 'Alundum' 46.H, running at 5,500 ft. per minute, and it lost ·001 inch in diameter on every tube. The speed of the work was 30 ft. per minute.

These examples are given as indicating an amount of reduction in wheel size which should not be exceeded under ordinary conditions. (*Churchill Machine Tool Co. Ltd.*)

Grinding Allowances.

(For Norton and Heald Grinding Machines.)

Frequent inquiries as to the amount of stock which should be left on turned and bored work to be ultimately finished to size by grinding had led to the answer that this depends on several factors which must be ascertained before a correct allowance can be determined. The object aimed at should be to so proportion the work between the lathe and the grinding machine that the total time taken by both in producing the desired degree of finish and accuracy is reduced to the minimum.

In a desire to turn out a 'good job' the turner sometimes overlooks the fact that a smooth piece of work having only a small allowance may take as long to finish in the grinding machine as a rough-turned job on which more metal is left.

The chart, fig. 7, shows the grinding allowances which are recommended for turned or bored work up to 12 ins. diameter. Although the amounts specified may, to some, appear excessive, they may be allowed with confidence in establishments possessing a grinding department run according to modern ideas of efficiency and lathes sufficiently powerful to take the coarse feeds recommended.

Curves A and A¹ show maximum and minimum amounts to be left on the diameter of rough turned work over 12 diameters long.

Curves B and B¹ show maximum and minimum amounts to be left on the diameter of rough turned work under 12 diameters long.

Curves C and C¹ show maximum and minimum amounts to be left on diameter of smooth turned and bar-lathe work over 12 diameters long.

Curves D and D¹ show maximum and minimum amounts to be left on diameters of smooth turned and bar-lathe work under 12 diameters long.

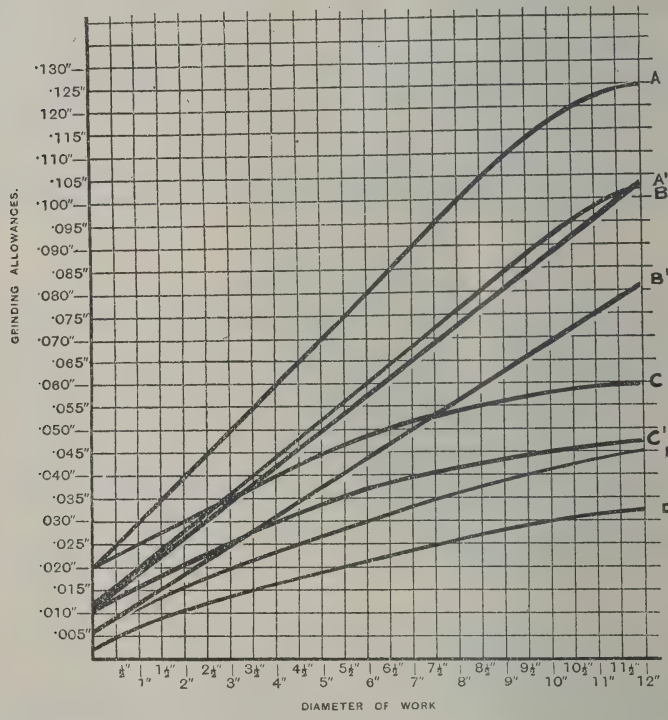

FIG. 7.—Grinding Allowances for Norton Cylindrical Grinding Machines.

NOTE.—By 'rough turned,' is meant work having coarse traverse marks, the measurements being taken on the top of the ridges. The following are the finest feeds which should be employed :—

For work up to 2 ins. diameter	30 per inch.
For work from 2 ins. to 4 ins. diameter	20 ,,
For work from 4 ins. to 8 ins. diameter	16 ,,
For work from 8 ins. to 12 ins. diameter	8 ,,

Case-hardened work is an exception, because the finish must be fairly smooth to allow regular penetration of the casing compound. Use curves C and C¹ for all such work.

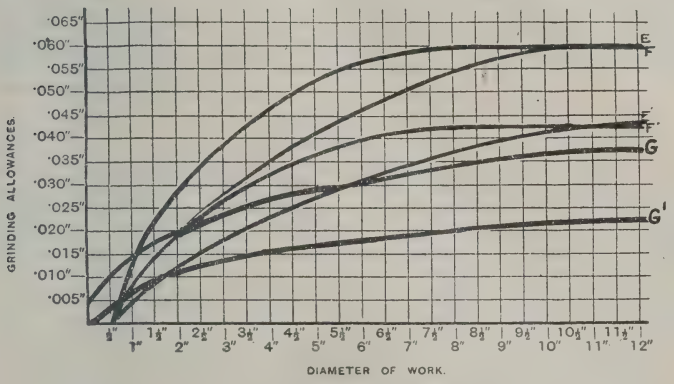

FIG. 8.—Grinding Allowances for Heald Internal Grinding Machines.

Curves E and E′ (fig. 8) show maximum and minimum amounts to be left in the bore of mild steel work that is to be case-hardened before grinding.

Curves F and F¹ show maximum and minimum amounts to be left in the bore of carbon or high-speed steel work that is to be hardened before grinding.

Curves G and G¹ show maximum and minimum amounts to be left in the bore of soft work, whether steel, cast iron, or brass.

NOTES.

The following explanatory notes will serve to show the theory followed out, and will assist in determining allowances for the exceptional jobs which will occasionally present themselves :—

Taking first *external work*, as being the more common, it will be noted that a larger allowance is made on articles which exceed twelve diameters length than in the case of shorter jobs. This is to save lathe work.

A job over twelve diameters long will spring considerably under a good cut, and there is a possibility of bends making their appearance. The largest possible allowance is therefore made on this work, so that the turner need not waste the time which would be taken in producing articles more nearly parallel and straight.

Then, again, a distinction is made between rough-turned work and that which is produced by a fine feed or made on turret lathes with a box tool.

For all work turned between centres, with the exception of that which is to be carbonised for case-hardening, the use of a coarse traverse is advocated, the finest feed per inch that should be used for various diameters being specified on the chart. Work which is to be carbonised must be turned with a fairly smooth finish, so as to allow regular penetration of the casing compound ; therefore the allowance specified for smooth work over twelve diameters long should be used for case-hardened work whatever its length. If such work is hollow it may distort after quenching, therefore great care must be exercised in hardening, as the allowance above specified cannot be exceeded or the hard skin would be entirely removed in grinding to size.

The allowance for carbon and high-speed steel work which is hardened will be the same as that provided for soft work, as any distortion which occurs must be corrected in the straightening press before grinding.

Internal work, which is dealt with by the lower portion of the chart, is divided into three classes as follows :—

1. Mild steel case-hardened.
2. Carbon or high-speed steel hardened.
3. Soft work, whether steel, cast iron, or bronze.

Hardened and case-hardened work in which the hole is less than half an inch in diameter should, as shown in the chart, be bored or reamed to standard size, as there will be a sufficient

shrinking when the quenching takes place to provide a grinding allowance. It will be noted that the amount allowed in case-hardened work increases very rapidly up to 6 ins. diameter; this is to allow for distortion in hardening. Above this size the increase is slow, and care should be taken to avoid excessive distortion, as no larger allowance can be made, otherwise the hard skin would be removed by the grinding operation. In determining the allowance for soft work it should be remembered that the class of finish given to the hole will decide whether the high or low limit should be worked to. Thus, in holes which are rough drilled or bored, the allowance should approach the maximum, whilst in reamed holes the minimum allowance should be left.

(*Alfred Herbert Ltd., Coventry.*)

Polishing.

For grinding and polishing *marble*, *stones*, and *glass*, crushed steel has proved very satisfactory, on account of its hardness, sharpness, and toughness. It is, however, but little used in this country, sand, carbide, or aluminous abrasives being generally employed. For cutting stone, marble, and glass, a metal wheel with loose sand and water is largely employed, but grinding wheels of carbide and aluminous abrasives of medium grade and 36–50 grit are being increasingly employed. For producing a rough surface on glass, sand is largely used in what is known as the sand-blast process.

For *smoothing wood* and similar materials, garnet-emery and sand, mounted on paper or cloth, are largely employed, garnet being especially suitable for hard woods. For finishing wooden handles, sand mounted in endless belts is largely used.

In the leather industries, and especially in the manufacture of boots and shoes, corundum and carborundum cloths are largely used for heel scouring and breasting and for buffing.

For work in which an *exceptionally hard abrasive* is required, including the truing of abrasive wheels, diamond bort or carbonado are employed.

For polishing steel articles, blocks of carbide or aluminous abrasive or cloth or paper covered with emery or corundum is largely employed.

For polishing other metals, glass, etc., loose powders are employed. Such powders may be used in the dry or wet state, and may be rubbed on to the material to be polished, or they may be applied by means of a wheel (or 'dolly') composed of discs of cloth.

For polishing brass and other softer metals, very fine silica, quartz flour, emery carbide or aluminous abrasives, crocus, rouge, or whiting are employed. For silver and gold well-slaked lime is largely used. The polishing powder is sometimes treated with rouge to disguise its nature and to give white metals a slightly ruddy tint, which improves their appearance.

In the so-called liquid polishes, a little oxalic acid or other chemical detergent is sometimes added to the abrasive powder, or to the liquid in which the latter is suspended.

Sand Blasting.

The air pressures used for different materials are, approximately, as follows:—Steel castings or forgings, 80 to 100 lbs.; malleable iron, 70 to 85 lbs.; cast iron, 60 to 70 lbs.; and brass and aluminium, 35 to 50 lbs.

For some classes of work a small nozzle opening, that is, a fine strong jet, may be desirable; for other work a broader stream, covering a larger surface but working at a lower pressure may be best. Table I. gives the relation between air flow in cubic feet of free air per minute at varying pressures, and the horse-power required to produce them by single-stage compression, for nozzles ranging in diameter from $\frac{1}{8}$ to $\frac{3}{8}$ in. inclusive.

Typical cylinder dimensions, together with the displacement and the horse-power required to develop various amounts of air pressure, are given in Table II.

In cases where there is moisture in the air, it is well to make provision for the elimination of the moisture by installing a moisture separator or a suitable heater.

Sand is the most commonly used abrasive on account of its relatively low price. Ordinary sand is inferior to sea sand and silica sand, as the two latter possess greater hardness and are therefore more lasting. Abrasives such as steel grit and shot are used to a certain extent, and the use of these more expensive abrasives is warranted under certain conditions. For classes of work such as electro-plating or galvanising, the metallic dust adhering to the work would make its use prohibitive, because it prevents perfect galvanising, although no difficulty is experienced in this respect with sand.

There is no one abrasive that is best adapted to all classes of work. A selection must be made with due regard to reclaiming means, to greatest economy in operation and to maximum production. By making tests with various materials, and keeping accurate records of quality of work, output, life of the abrasive, and so on, the one best suited for the individual application is readily determined. Such tests have shown metal abrasives to have about sixty times the

life of sand. This apparently large percentage may, however, be offset to a great extent by losses of abrasive in operation or in handling. In good steel foundry practice these losses may be kept as low as 10 per cent., while the average loss due to disintegration, for different grades of sand, amounts to about 20 per cent. per month. The reduction in cleaning time resulting from using metal abrasives instead of sand varies, of course, but a gain of about 15 to 20 per cent. in time appears to be in line with actual practical experience. Metal abrasives do not require large sand-storage bins and have the added advantage of producing less dust, thereby improving the general working conditions.

TABLE I.—FLOW OF FREE AIR FOR DIFFERENT SIZES OF NOZZLES.

Diameter of Nozzle. Ins.	Pressure (cub. ft. per min.) and Corresponding Horse-power Required. 20 lbs.	H.P.	30 lbs.	H.P.	40 lbs.	H.P.	50 lbs.	H.P.

TABLE II.—CYLINDER DISPLACEMENTS AND HORSE-POWER REQUIREMENTS OF AIR COMPRESSORS.

Cylinder. Diam. Ins.	Stroke. Ins.	Revs. per min.	Piston Displacement. Cub. ft. per min.	Horse-power Requirements. Pressure (cub. ft. per min). 50	60	70	80	90	100
6	6	300	57	7	7·5	8·5	9·0	9·5	10
8	8	260	118	14	15·5	16·8	18·0	19·0	20
10	10	235	210	24	27·0	29·0	31·0	33·0	35
12	12	220	340	45	50·0	54·0	58·0	62·0	65

All abrasives should be screened each time before using, to remove particles large enough to clog the nozzle, and also to eliminate fine particles which only produce dust and have no abrasive quality, but which consume some of the pressure. Screen separators, frequently operated by compressed air, may be used for this purpose. (*Abstract, C.M.S.*, '*Machinery*,' *Jan.* 13, 1921.)

SECTION XX

PART III

STEAM-HAMMERS.

(Messrs. B. & S. Massey, Ltd., Openshaw.)

Three standard types of steam-hammer are made by B. & S. Massey, Ltd.—the 'Overhanging Form with Slides' the 'Arch Form with Slides,' and the 'Rigby type without Slides.' All these hammers can be made suitable for driving by compressed air instead of steam.

Overhanging Form with Slides.

These hammers (fig. 1) are usually preferred for general smith-work. The anvils are accessible to the workman from three sides, and the tups are supported and accurately guided by the slides, making it possible to do accurate stamping in dies.

Each hammer has two separate standards, with a space between them, through which long bars can be passed. All the hammers are double-acting and are fitted with equilibrium working valves.

Up to and including the 12-cwt. size, the hammers are fitted with a combined self-acting and handworked valve gear; the 15 cwt. and larger sizes are ordinarily fitted with Massey's Patent Handworked Expansion Valve Gear, but a combined self-acting and handworked gear can be fitted if desired

The pistons, which are forged solid with the piston-rods, are fitted with steel piston-rings. The palletts are made of tough steel with planed and hardened faces.

The anvil blocks are about 8 times the weight of the falling mass, and in the 12 cwt. and smaller sizes they are turned to fit the bored baseplates; this greatly increases the efficiency of the hammers when it is desired to use them for stamping in dies.

(*b*) Average on mixed blows	203 lbs.	230 lbs.	270 lbs.	330 lbs.	385 lbs.

* All these figures are necessarily rough approximations.

They are meant to apply to average engineers' smithwork, and are for efficient results on this class of work, with a steam pressure of about 60 lbs. per sq. in.

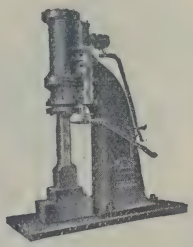
Even for this they may, at a pinch, be exceeded 10 per cent.

There are many classes of work which require much larger hammers, and some classes which require smaller hammers than those indicated, owing chiefly to the varying amount which has to be done at a heat.

† Steam Consumption.

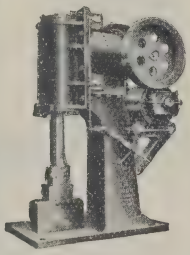
A steam pressure of about 60 lbs. per sq. in. is assumed.

During ordinary forging there are many blows of less than full force and there are also necessary pauses (holding up) for adjusting work or tools during a heat.



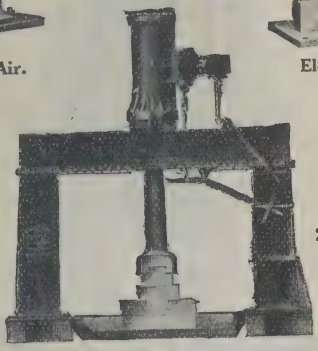
While line (*a*) above gives the consumption on continuous hard blows only, line (*b*) gives the consumption as ordinarily reduced by these circumstances. Further, under average smithy conditions, a hammer may be assumed to be actually in motion about 15 minutes in every hour, and the figures given above (in line 6) are based on this assumption.

The 'RIGBY'S PATENT' Hammers



both for Steam and Compressed Air, still maintain their High Reputation for Productive Efficiency, in spite of various attempts at imitation.

ASK ANY PIECE-WORK SMITH WHO HAS HAD THE GOOD FORTUNE TO WORK UNDER ONE.



We have equipped many of the largest Railway Workshops and Shipbuilding Yards both at Home and Abroad, with our well-known Hammers, and our many conversions from steam to air, are giving great satisfaction.

For Steam or Air.

Electric Drive.

Girder Hammer.

In sizes from 2 tons upwards.

IMPORTANT—We are the Patentees and Sole Makers of the '*RIGBY'S PATENT*' Hammer, and all Hammers manufactured by us bear our Trade Mark '*RIGBY'S PATENT*' cast on the columns.

F. 1023

Where the hammers are fitted with Massey's Patent Handworked Expansion Valve Gear, these figures can be reduced by 20 to 25 per cent.

In cases in which one boiler is put down solely to drive one hammer, the capacity of such boiler should be fixed according to line (*a*), page 1022, because otherwise the pressure would fall too low during a normal run of hard blows.

Arch Form with Slides (Fig. 2).

These hammers, fig. 2, are made in sizes ranging from 3 cwt. to 19 tons and over, and the design provides a maximum of strength and rigidity. The 15 cwt. and larger sizes are fitted with Massey's Patent Handworked Expansion Valve Gear.

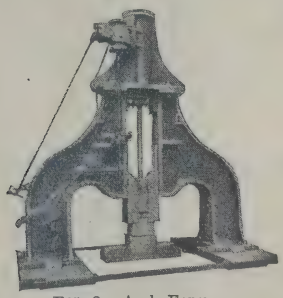

Fig. 2.—Arch Form.

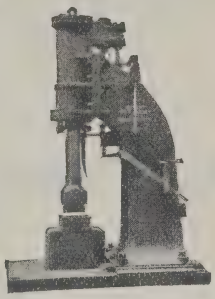

Fig. 3.—Rigby Type.

Rigby Type without Slides (Fig. 3).

These hammers, fig. 3, which are made in sizes from 3 cwt. to 3 tons, are particularly suitable where forgings of large size and awkward shape have to be dealt with. The strokes are longer and the cylinders larger in diameter than in the other forms described. All sizes are fitted with Massey's Patent Handworked Expansion Valve Gear.

Energy and Velocity of Blow.

If a = area of piston, in square inches; p = average pressure of steam on piston during downward stroke, in pounds per square inch; S = stroke of piston, in feet; W = falling weight in pounds; E = energy of blow after full stroke and before striking, in foot-pounds, friction being neglected.

$$E = (ap + W)S.$$

P = total pressure on piston = pa; F = total force causing downward acceleration = P + W = pa + W; g = acceleration due to gravity = 32·2; V = velocity after full stroke and before striking, in feet per second, friction again being neglected.

$$V^2 = \frac{2FgS}{W}.$$

No commercial use is made of these calculations, either for the naming of sizes of hammers or for any other purpose.

The question is sometimes asked: *What weight of blow does the hammer strike?*

The force of a blow cannot be stated in terms of weight at all, because the pressure of a weight is continuous, whereas the force of a blow is expended in a moment. It has, however, been ascertained, by careful experiments, that the maximum blow of a 5-cwt. double-acting steam-hammer, with moderate steam pressure, produces a crushing effect upon a piece of hot iron as great as that produced by a load of about 30 tons, and a ½-cwt. double-acting steam-hammer a crushing effect equal to that produced by a load of about 2½ tons.

Naming Sizes of Steam-hammers.

In naming the sizes of steam-hammers no account is taken of the pressure of steam upon the piston. Thus, a 5-cwt. hammer is one in which the falling mass weighs at least 5 cwt., but of course the force of the blow is greatly increased by the pressure of steam above the piston accelerating the fall.

Foundations.

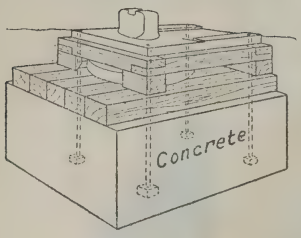

FIG. 4.—Typical Foundation for Steam-Hammers of the Overhanging Form.

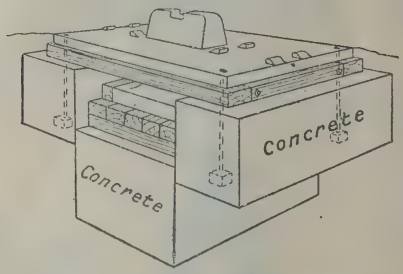

FIG. 5.—Typical Foundation for Steam-Hammers of the Arch Form.
(*B. & S. Massey, Ltd.*)

PNEUMATIC POWER HAMMERS.

THE MASSEY IMPROVED PNEUMATIC POWER HAMMER.

These hammers (fig. 6) are arranged for belt or for direct electric drive. They are similar to steam-hammers in many respects, and are about equal to them in working capacity, assuming the steam-hammers to be working under ordinary conditions of pressure, etc.

It is very important to note that the size name of each hammer indicates the true weight of its falling parts.

The anvil block is set diagonally, to enable long bars to be worked in either direction.

The essential parts of the hammer are two cylinders connected by air passages which are governed by a valve under the control of the operator.

When the bypass A (fig. 7) is closed, the reciprocating movement of the pump piston is transmitted to the hammer by the air, which is forced alternately to the top and bottom sides of the hammer piston, through passages B and C.

If A be opened, the air flows backwards and forwards through the bypass, and the hammer remains at rest.

To hold the hammer up at the top of its stroke the valve is turned so that two one-way valves are brought into play, and the air is forced into and retained in the lower part of the hammer cylinder.

In another position of the valve, the above action is reversed, with the result that a partial vacuum is formed below the hammer piston and the hammer is therefore held firmly down on the anvil.

(*B. & S. Massey, Ltd.*)

PLAYER'S PNEUMATIC POWER HAMMERS.

(*Messrs. W. & J. Player.*)

These hammers, for forging, swaging, riveting, and planishing, are made in various patterns.

General Forging Hammers

Are on the double cylinder principle, in which one cylinder is used as a pump to actuate the piston in the other or hammer cylinder. The design of the hammer is similar in the hammer part to that of a steam hammer, with heavy base plate through which a separate anvil comes, which is kept from turning by keys, but is free to give vertically to the shock of the blows, without transmitting the shock to the baseplate or hammer.

The frames are of heavy design, in cast iron, with separate adjustable V slides for the tup to run in.

There is ample space between the tools and the frames, the latter being open so that long bars can be put through if necessary. The piston, rod, and tup are of mild steel forgings, following steam hammer practice. The cylinders and valve chamber are cast in one piece, and the valve is a cylindrical one. The design of the valve control is such that the hammer will strike heavy or light blows, stop up or stop down at will, whilst the power used is proportionate to the force of the blows.

The hammers can be driven either by belt, or by direct electric motor drive through gearing, and are made with striking masses of 1, 2, 3, 5, 7, and 10 cwt.; they are claimed to be equal in effective working to similar sizes of steam hammers under ordinary steam pressure, but to be much more economical in working.

Forging Hammers,

For drawing down, swaging, edge tool making, etc. For work requiring a rapid short stroke, a range of hammers is made with an air-cylinder control, by which all shock of the blow is taken from the working parts, and the force of the blows controlled from zero to the heaviest possible, whilst the hammer is working.

The base plate, anvil, and bottom part of the frames are of the usual steam hammer type, but the top of the frames carries a crank shaft which operates an air cylinder running in slides on the frames.

In the cylinder is the piston and rod, the latter carrying the tup. The piston is driven by the air cushions above and below it, which act as springs, and enable the piston to take a much longer stroke than the cylinder does. A valve gear on the cylinder regulates the amount of air above and below the piston, and, by varying this, enables the force of the blow to be perfectly regulated.

This type of hammer is made in 40 lbs., ¾, 1½, 3, 5, and 7 cwt. sizes, and is largely used for shovel and hoe plating, being made with arch frames for these purposes. They are also employed for edge tool forging, ship slip drawing, tube tagging and tapering, swaging, etc.

Riveting Hammers.

Small hammers of this description are constructed to deal with rivets ⅛ in. and under, and other sizes for rivets up to 2 ins. diameter, in the cold state.

The arrangement is that of a cushion air-cylinder hammer of similar type to that used for edge tool forging, but the riveting tool is made to revolve, and is so shaped as to operate on only a small portion of the head of the rivet at each blow, the rotation of the tool gradually

working it all round the rivet head to finish it. Snap head, cup head, or flat head riveting can be done according to the shape of tool used, and as the air-cushion control takes the blow off completely when required, it is not necessary to stop the hammer when putting the work in and out. The hammers are successfully working on chain work, cycle pedals, wrought-iron pulleys, agricultural machinery, wheels, and parts, etc.

Planishing Hammers.

For sheet metal work in which a quick running sharp blow is required, a special type of power hammer is made, in which the head is actuated by a rocking lever, this in turn being reciprocated by a crank pin. The head consists of a cylinder bored out of a solid forged steel block which works in adjustable slides on the frame of the hammer. The cylinder has two slots in its sides, and a phosphor bronze piston the length of the slots fits in the cylinder, so that an air cushion is formed top and bottom as soon as the ends of the piston pass the ends of the slot. The piston is driven by a rocking shaft by means of a pin passing through the slots, the end of the rocking shaft being forked to carry the pin. The piston, as it moves, causes the head to take its stroke by means of the air cushion inside it, and these air cushions prevent any shock of the blow being communicated to the rocking shaft or any other working part. The rocking shaft works on a fulcrum which can be moved nearer to or further away from the head, so that the stroke can be regulated for either heavy or light blows. The fulcrum works in a slot of such an inclination that the blow, whether long or short, comes to the same place at its lowest point.

A special feature in the design is that the down-stroke of the head takes place in less than half the revolution of the crank pin, so that a very sharp blow is struck.

This type of hammer is largely in use for coppersmith's work, being made in sizes to work copper from $\frac{1}{16}$ in. to 1 in. in thickness; the frames are in suitable designs for fixing to the floor, wall, or overhead beams. Suitable anvils for cylinder, bowl, and curved work are also made.

Special designs are constructed for dealing with the special curves, etc., for motor car panel work in steel, aluminium, etc., and large sizes for heavy sheet steel work, for ventilator cowls, and similar work.

Compressed Air Hammers.

In order to produce an air-driven hammer of the greatest possible efficiency attention must be given to the following points:—

The reduction of clearance losses;

The reduction of back pressure losses;

The expansive use of the air;

The prevention of afterflow into the cylinder after the blow has been struck.

The choice of a suitable pressure.

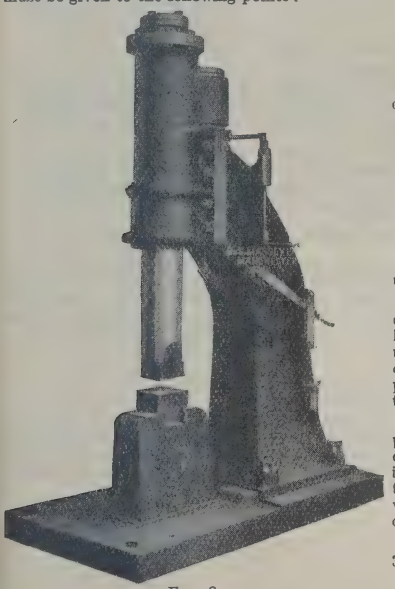

FIG. 8.

THE MASSEY PATENT COMPRESSED AIR HAMMER.

(Fig. 8.)

Method of Working.

The underside of the piston is always acted upon by the pressure of air from the supply.

A port connects the upper portion of the cylinder with a point about half-way down its length. When, therefore, the piston is at the upper half of its stroke there is a free passage of air from the supply to the upper side of the piston through this port, and the hammer is thrown down.

On passing the lower end of the port the piston cuts off the supply, and the remainder of the stroke is done expansively. The cycle is completed by exhausting the expanded air to atmosphere by a movement of the valve, when the hammer will rise under the influence of the constant pressure below the piston.

These hammers are made in sizes from 3 cwt. to 30 cwt.—weight of falling parts.

The hammers are designed for a pressure of 50 to 60 lbs. per sq. in., and though they may be modified to suit higher pressures these are not recommended for economical working.

(*B. & S. Massey, Ltd., Openshaw.*)

DROP STAMPS.

The Massey Friction Drop Stamp.

The practice of Stamping, in Dies, parts which have to be made in large numbers, such as motor-car parts, railway wagon parts, etc., etc., has become very general, and the tool usually adopted for this purpose in this country is the 'drop stamp.' Latterly, the friction lifted type of drop stamp (fig. 9) has tended to supersede the steam lifted type, on account of the improved control, the greater efficiency, and the smaller cost of up-keep.

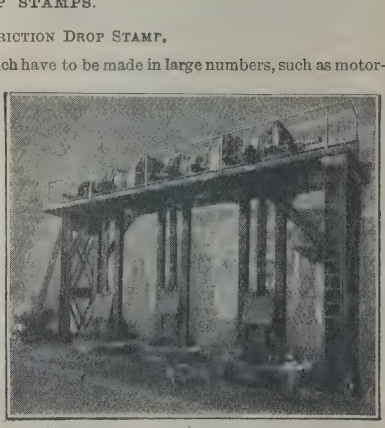

Fig. 9.—Battery of 30-15-20 cwt. Friction Drop Stamps.

General Construction.

The usual plan is to have two, three, or four drop stamps of different falling weights arranged in a battery. The lifting mechanism in this case is mounted on girder work supported on stanchions, while the falling weight or tup is guided by vertical rolled steel guides resting in recesses in the anvil block, and supported at their upper ends by the girder work in such a way as not to transmit shock to the lifting mechanism.

Details of Friction Lifters.

The lifters themselves resemble a band brake in construction. A steel brake band lined with suitable material, and connected with the lifting arm, is made to grip a constantly revolving drum by means of a lever actuated by hand through a pulling cord, and the tup is thereby raised. As soon as the tension on the cord is released, a spring disengages the band, and the tup falls under the influence of gravity.

A special arrangement is adopted by means of which the grip of the friction band is automatically reduced as the tup rises, thereby making it necessary to maintain a constant pull on the cord in order to prolong the rise of the tup; when, moreover, the cord is held stationary, the tup remains suspended at the point to which it may have been raised, and as stated above, the tup falls when the tension on the cord is released.

It will therefore be seen that a very intimate relation exists between the movements of the tup and those of the pulling cord.

The movement of the hand is only a short one, and the pull required is very slight, but every movement of the hand is reproduced on a larger scale by the tup. Those who are familiar with the old-fashioned kick stamps in which a heavy pull was required the whole length of the stroke, and which sometimes required two or three men to act as pullers, appreciate very highly the action of friction stamps in which a control as excellent as in the kick stamp is secured with so little labour on the part of the operator.

Method of Driving.

The friction lifters are generally mounted on shafts driven by spur gearing from a quick-running back shaft. A flywheel which also serves as a driving pulley is mounted on one end of the back shaft and supplies the reserve of power needed at the moment of picking up the tup.

The drive is usually taken direct from an electric motor placed either on one of the stanchions or in the larger sizes on the floor, or in some other convenient position.

SCREW THREADS AND SCREWS—BOLTS AND NUTS—LOCK NUTS—SPANNERS—PIPE FLANGES—KEYS—SCREW TAPS—COUPLINGS—PULLEY ARMS AND BOSSES.

(Revised and amplified by Dempster Smith, M.Sc., M.I.Mech.E.)

SCREW THREADS AND SCREWS.

Forms of Screw Threads.

Figs. 1, 2, 3, and 4 show four usual forms of thread, each of 1 inch pitch.

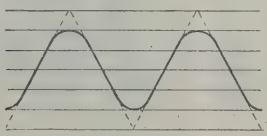

FIG. 1. Whitworth Thread-form.

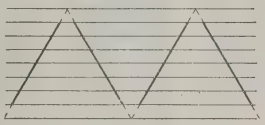

FIG. 2. American Thread-form.

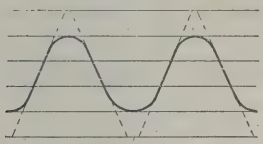

FIG. 3. Swiss Thread-form.

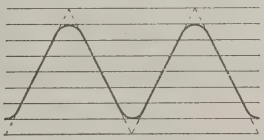

FIG. 4. Steinlen Thread-form.

In the *Whitworth* or *English Standard* thread (fig. 1) the angle made by the two sides of the thread is 55° for all sizes of thread. One-sixth of the depth of the triangle is rounded off the top and bottom, so that the angle of 55° gives for the actual depth rather more than three-fifths and less than two-thirds of the pitch.

In the *American* (*Sellers'*) thread (fig. 2) the angle made by the two sides of the triangle is 60°, and one-eighth of the depth is cut off the top and bottom of the triangle, leaving a flat one-eighth of the pitch in width.

In the *Swiss* or *Thury* thread (fig. 3) the angle made by the two sides of the thread is 47½°, and one-fifth of the depth is rounded off the top and bottom of the triangle.

For screw-plate Swiss threads the depth of the thread is three-fifths the length of the pitch.

The top of the ridge is formed by a circular arc (*a*), the radius of which equals one-sixth of the pitch. The space between two consecutive ridges is formed at the side next the core by a circular arc (*b*), the radius of which equals one-fifth of the pitch.

The Swiss thread for screws made in the lathe is the *Steinlen* thread (fig. 4). The angle made by the two sides of the thread is 58° 8′, and the radius of the connecting arcs is ·1011 of the pitch. The generating figure is an isosceles triangle, of which the base and the height are equal to the pitch. One-eighth of the depth is rounded off the top and bottom of the triangle.

The *British Association* thread is similar to that of Thury, except that the top and bottom of the threads are both rounded to the same radius, namely, two-elevenths of the pitch.

BRITISH STANDARD FINE (B.S.F.) SCREW THREADS AND THEIR TOLERANCES.*

(No. 84—1918.) (*Abstract.*)

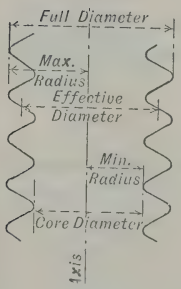

FIG. 5.

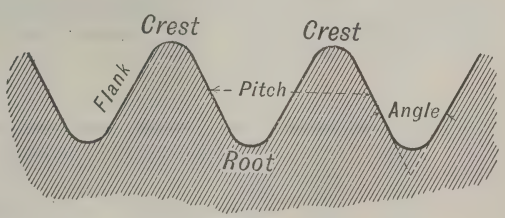

FIG. 6.

Effective Diameter of a Screw.—The effective diameter of a perfect screw having a single thread is the length of a line drawn through the axis and at right angles to it, measured between the points where the line cuts the flanks of the thread (fig. 5).

Core Diameter.—The core diameter is twice the minimum radius of a screw, measured at right angles to the axis (fig. 5).

NOTE.—From fig. 5 it will be seen that the 'core diameter' of the male thread is measured between the roots of the thread; it should be borne in mind, however, that the 'core diameter' of the female thread, being approximately the same dimension, is measured between the crests of the thread.

* By permission of the British Engineering Standards Association.

Full Diameter.—The full diameter is twice the maximum radius of a screw, measured at right angles to the axis (fig. 5).

Crest.—The crest is the prominent part of the thread, whether of the male screw or of the female screw (fig. 6).

Root.—The root is the bottom of the groove of the thread, whether of the male screw or of the female screw (fig. 6).

Flank of Thread.—The flank of the thread is the straight part of the thread which connects the crests and roots (fig. 6).

Angle of Thread.—The angle of the thread is the angle between the slopes, measured in the axial plane (fig. 6).

Pitch.—The pitch is the distance in inches or millimetres measured along a line parallel to the axis of the screw between the point where it cuts any thread of the screw and the point at which it next meets the corresponding part of the same thread (fig. 6). *The reciprocal of the pitch* measures the number of turns per inch or millimetre, as the case may be.

Recommendations.

Form of Thread.

1. The Association recommend that the Whitworth form of thread, as defined in clause 2, be adopted on all screws of $\frac{1}{8}$in. diameter and above, having British Standard Fine Pitches.

Definition of Whitworth Form of Thread.

2. The following defines the Whitworth thread :—

The *Whitworth Form of Thread* is one in which the angle between the flanks, measured in the axial plane, is 55° ; one-sixth of the sharp triangle is truncated at top and bottom, the threads being rounded equally at crests and roots to a radius which is therefore 0·137329 times the pitch ; the depth of the thread is 0·640327 times the pitch.

Tolerances.

—	Full Diameter.	Effective Diameter.	Core Diameter.
Bolt	$3\times\cdot01\sqrt{p}$	$2\times\cdot01\sqrt{p}$	$4\times\cdot01\sqrt{p}$
Nut	$4\times\cdot01\sqrt{p}$	$2\times\cdot01\sqrt{p}$	$3\times\cdot01\sqrt{p}$

The corresponding tolerances on grade and play are :—

$$\text{Grade}=4\times\cdot01\sqrt{p}\ ;\quad \text{Play}=2\times\cdot01\sqrt{p}.$$

In addition, a uniform allowance of 2 thousandths of an inch has been made throughout between the maximum bolt and the minimum nut.

For much work the above tolerances are too large. A second series of tables have therefore been formed by halving the tolerances everywhere. The Association recommend that threads made in accordance with these dimensions be known as ' British Standard Fine Threads (Close Fits).'

The basis of calculation of these tolerances is given below.

—	Full Diameter.	Effective Diameter.	Core Diameter.
Bolt	$1{\cdot}5\times{\cdot}01\sqrt{p}$	$\cdot01\sqrt{p}$	$2\times{\cdot}01\sqrt{p}$
Nut	$2\times{\cdot}01\sqrt{p}$	$\cdot01\sqrt{p}$	$1{\cdot}5\times{\cdot}01\sqrt{p}$

The corresponding tolerances and allowance are :—

Grade tolerance $= 2\times{\cdot}01\sqrt{p}$; play tolerance $=\cdot01\sqrt{p}$; allowance $= 0{\cdot}002$ in.

The pitches given in the following table are based on the following formulæ :—

For sizes up to and including screw threads of 1 inch diameter, $P=\frac{\sqrt[3]{d^2}}{10}$.

For sizes above 1 inch diameter, up to and including screw threads of 6 ins. diameter, $P=\frac{\sqrt[3]{d^5}}{10}$

$$\text{Pitch} = \frac{1}{\text{No. of threads per inch}}\text{; depth of thread} = 0{\cdot}640327 \times \text{pitch;}$$

Rounding at crest and root $= 0{\cdot}137329 \times$ pitch.

Comparison of U.S. Standard and Whitworth Screw Threads.

The difference in form that exists between the Whitworth and the U.S. standard screw thread is shown in fig. 7. The comparison is based upon a screw with 1 thread per inch. Clearances and interferences for the two forms of threads having any other pitch may therefore be obtained by dividing the respective values given in the diagram by the number of threads per inch under consideration.

In order to fit a U.S. standard screw into a Whitworth tapped hole or nut, round the outside corners of the screw and change the outline of the thread below the pitch line by slightly filing the flanks. These changes are indicated in the figure by the sectional areas. If it is desired to fit a Whitworth screw into a U.S. standard tapped hole or nut, drill out the hole or nut, using a drill which is larger than the tap drill required for an equal size U.S. standard tap, as shown by

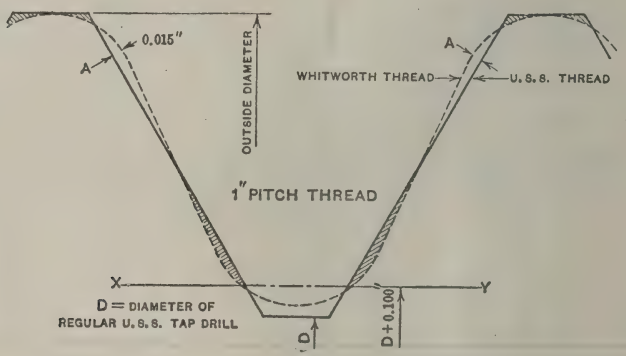

FIG. 7.

the line XY in the diagram. For 1 thread per inch, this increase in diameter of the tap drill will be 0·100 inch, and for other numbers of threads the amount of increase will be found by dividing 0·100 inch by the number of threads per inch. Thus, for 10 threads per inch, 0·100 ÷ 10 = 0·010 inch. The flanks of the Whitworth thread above the pitch line are then filed slightly as indicated at A in the illustration.

The methods mentioned are recommended only for fastening screws and ordinary threaded parts, and should not be employed where accurate threads are required.

INTERNATIONAL SYSTEM OF METRICAL SCREW THREADS.

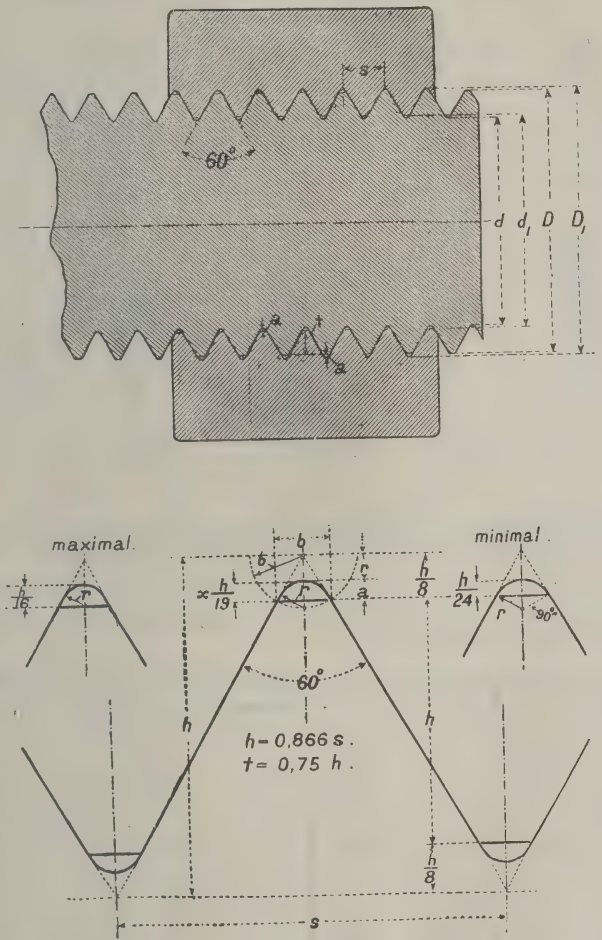

FIG. 8.

Wood Screws.

(Sometimes termed 'Screw Nails.')

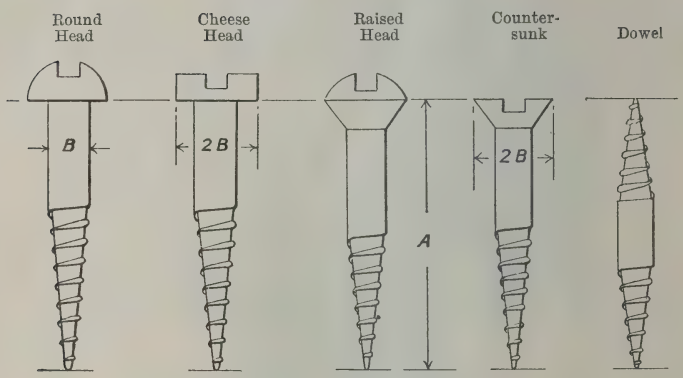

FIG. 9.

Wood screws are measured, as regards length (A), from the point to the portion normally flush with the surface of the material into which they are driven. Dowel screws are measured from point to point.

The number (size or thickness) (B) refers to the diameter of the shank or neck, and for screws of Nettlefold's manufacture is as follows :—

Number.	Diameter.	Number.	Diameter.	Number.	Diameter.	Number.	Diameter.
	In.		In.		In.		In.
1	·066	9	·178	17	·290	25	·402
2	·080	10	·192	18	·304	26	·416
3	·094	11	·206	19	·318	27	·430
4	·108	12	·220	20	·332	28	·444
5	·122	13	·234	21	·346	29	·458
6	·136	14	·248	22	·360	30	·472
7	·150	15	·262	23	·374	31	·486
8	·164	16	·276	24	·388	32	·500

Formula for ascertaining diameter of screw :—

$$(\cdot 014 \times \text{No.}) + \cdot 052 \text{ in.} = \text{diameter.}$$

Example :—$(\cdot 014 \times 16) + \cdot 052$ in. $= \cdot 224 + \cdot 052 = \cdot 276$ diameter of No. 16.

The diameter of the head may be taken as twice the thickness of the neck.

Numerous lengths are obtainable in each size from ¼ in. in the smaller sizes to 9 ins. in No. 32.

Larger sizes are made to order but not gauged, and most sizes are obtainable in iron or brass.

Screw Heads.

BRITISH STANDARD HEADS FOR SMALL SCREWS.*

(No. 57–1920.) (*Abstract.*)

For all classes of head the diameter to be 1·75 times the full diameter of the thread.

The width of saw-cuts to be according to the formula,

$$S = \cdot 2\ D + \cdot 1m$$

where S = width of saw-cut, and D = full diameter of the thread in millimetres.

The standard depth of saw-cut to equal one-half the total depth of the head in all cases, such depth being measured at the centre of the head.

NOTES ON TABLE.

Columns 1 and 2 of the table give the nominal bore of the tube and the full diameter of the screw in the coupler for use with that tube. The diameter of this screw has been chosen, in all cases, so that the coupler can be screwed by hand on to the tube, leaving from four to eight threads exposed.

The Association have preserved the Old Whitworth Standards as far as possible in the simplified dimensions for screwing sizes on tubes up to $2\frac{1}{4}$ ins. nominal bore. The Association have been guided in fixing the gauge diameters of the larger screwing sizes by the advantages of making the outside diameters of the tubes even quarters of inches.

* By permission of the British Engineering Standards Association.

Bolts and Nuts.

According to the Whitworth system of standard sizes of bolts and nuts, the thickness of the bolt-head is seven-eighths of the diameter, and the nut is equal to the diameter.

In the Sellers' (American) system the heads and nuts are hexagonal, the thickness of the heads and of the nuts being equal to 1 diameter minus one-sixteenth inch. The breadth across the flats is equal to $1\frac{1}{2}$ diameters plus one-sixteenth inch.

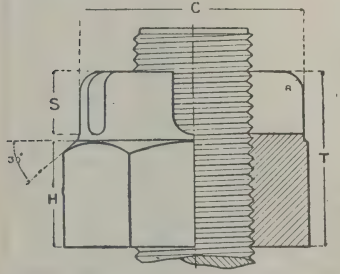
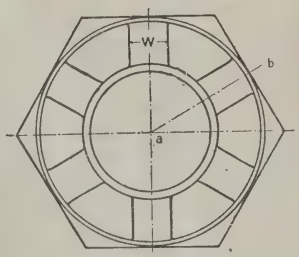
* By permission of the British Engineering Standards Association.



† The figures in this column represent the maximum width across the corners correct to two decimal places. The figures in italics are those for *black* nuts.

A chamfer of 30° from the face should be adopted on all bright nuts and bolt-heads. The interior diameter of the chamfer circle should not be appreciably less than the width across the flats.

In the common locking arrangement, in which a thick and thin nut are employed, the thin nut should have a thickness approximately equal to two-thirds that of the standard nut.



British Standard Castle Nuts.

Castle nuts should be provided with pin slots as shown in figs. 11, 12.

OUTSIDE ELEVATION. SECTIONAL ELEVATION a, b.

FIG. 11.

PLAN.

FIG. 12.

T = 1·25D; H = ·75D; S = ·4375D; C = width across flats − $\frac{1}{16}$ in.; where D = full diameter of thread on bolt.

TAPPING.

It is a common occurrence for a tap to break when tapping hard metal. If the tap is ground away on the point, so that the first five or six threads are gradually bevelled, the risk of breakage may be largely avoided. The effect of grinding the end of the tap is to break up the chips into smaller pieces, and thus prevent clogging the threads of the tap. This will be found to be especially advantageous in tapping very hard rolled steel. (*Mechanical World.*)

An easy rule for approximating tap-drill sizes is to deduct $1\frac{1}{2}$ times the pitch from the outside diameter of the tap. In the case of a $\frac{3}{8}$-in. tap, 16-pitch thread, for instance, $1\frac{1}{2}$ times $\frac{1}{16}=\frac{3}{32}$, and $\frac{3}{8}-\frac{3}{32}=\frac{9}{32}$ = the diameter of the drill required for a $\frac{3}{8}$-in. tap. (*Machinery.*)

CORRECT TAP GRINDING.

Grinding a tap consists usually of grinding the taper at the end of the tap, and the clearance back of the cutting edge thus formed. This taper may be long, as in nut taps; short, as in plug taps; or almost none, as in bottoming taps. The principle remains the same in each case. What is required is that each flute shall have exactly the same taper, just enough clearance so that it will cut freely, and not enough to needlessly weaken the cutting edge.

Prior to the advent of tap-grinding machinery nearly all taps were ground by hand, with a resultant lack of uniformity in taper and clearance. Fig. 24 shows a section of a four-flute tap with each flute ground differently in the matter of clearance or backing off. The flute A, at the left, is ground with a straight-line clearance just sufficient to have the heel of the flute actually clear and not drag. This calls for an angle of 15°, as indicated, and results in a weak cutting edge, but the strongest possible with a straight-line clearance at the heel.

The flute B, at the top, shows a 15° convex clearance. A glance shows this to be excessive. Flute C, at the right, shows a straight-line clearance of 5°, and nearly half of the flute at the back is not cleared at all, leaving the tap to ride on that portion and keep the front of the flute from cutting. Flute D, at the bottom, shows a perfect grind for ordinary work. It is a 5° convex clearance, and shows that with this small but sufficient clearance angle at the cutting edge, the back is perfectly cleared.

In addition to the correct clearance of taps, a uniform angle of taper for all flutes is necessary. The results of different tapers obtained by hand-grinding are indicated in fig. 24. Even a slight variation from the uniform taper angle means power wasted and taps broken. As the blunt

angle flute strikes the side of a drilled hole, it throws the cutting end of the tap off centre and imparts to it a wabbling motion. This means a tapped hole that is oversized, allowing the screw to fit loosely. Tap A is correctly ground and will tap a hole true to size, properly located and

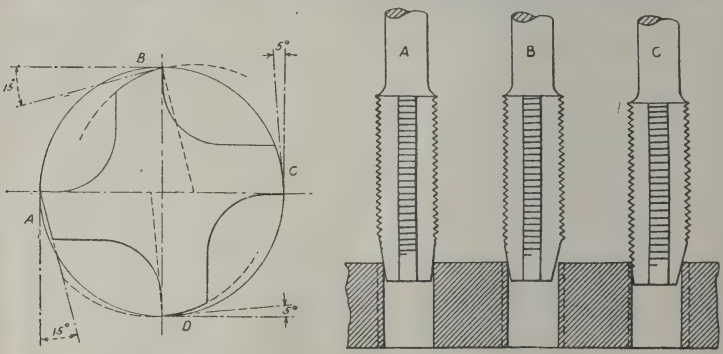

FIG. 24.

with smooth, accurately shaped threads. Tap B is ground with one flute at a more blunt angle than the other. This blunt flute is shown just as it strikes the drilled hole. Tap C shows a similar tap after it has been crowded over. The condition developed is readily seen.

(*'Railway Mechanical Engineer.'*)

PIPE THREAD TAP HEADS.

The Sheffield Small Tool Manufacturers have adopted the following list of sizes for the squares of pipe thread taps :—

No. of □.	Size of □. Inches.		Whitworth Thread Taps. Inches.	International Thread Taps. Millimetres.	Gas Tap. Inches.
	Fraction.	Decimal.			
0	$\frac{7}{64}$	·109	$\frac{1}{8}$	3 to $3\frac{1}{2}$	—
1	$\frac{9}{64}$	·140	$\frac{5}{32}$	4 to $4\frac{1}{2}$	—
2	$\frac{5}{32}$	·156	$\frac{5}{16}$	5	—
3	$\frac{13}{64}$	·203	$\frac{1}{4}$	6 to 7	—
4	$\frac{15}{64}$	·234	$\frac{5}{16}$ and $\frac{3}{8}$	8 to 10	$\frac{1}{8}$
5	$\frac{9}{32}$	·281	$\frac{7}{16}$	11 to 12	—
6	$\frac{5}{16}$	·312	$\frac{1}{2}$ and $\frac{9}{16}$	13 to 14	$\frac{1}{4}$
7	$\frac{25}{64}$	·390	$\frac{9}{16}$ and $\frac{11}{16}$	15 to 17	$\frac{3}{8}$
8	$\frac{29}{64}$	·453	$\frac{3}{4}$ and $\frac{13}{16}$	18 to 21	$\frac{1}{2}$
9	$\frac{35}{64}$	·546	$\frac{7}{8}$ and $\frac{15}{16}$	22 to 23	—
10	$\frac{41}{64}$	·640	1	24 to 26	$\frac{5}{8}$ and $\frac{3}{4}$
11	$\frac{23}{32}$	·718	$1\frac{1}{8}$	27 to 30	—
12	$\frac{13}{16}$	·812	$1\frac{1}{4}$	31 to 33	$\frac{7}{8}$ and 1
13	$\frac{27}{32}$	·843	$1\frac{3}{8}$	34 to 36	—
14	$\frac{29}{32}$	·906	$1\frac{1}{2}$	37 to 41	$1\frac{1}{4}$
15	$1\frac{5}{64}$	1·078	$1\frac{5}{8}$ and $1\frac{3}{4}$	42 to 46	$1\frac{1}{2}$ and $1\frac{3}{4}$
16	$1\frac{13}{64}$	1·203	$1\frac{7}{8}$ and 2	47 to 52	—
17	$1\frac{3}{8}$	1·375	$2\frac{1}{8}$ and $2\frac{1}{4}$	54 to 58	2 and $2\frac{1}{4}$
18	$1\frac{1}{2}$	1·500	$2\frac{3}{8}$ and $2\frac{1}{2}$	60 to 64	—
19	$1\frac{5}{8}$	1·625	$2\frac{5}{8}$ and $2\frac{3}{4}$	66 to 70	—
20	$1\frac{3}{4}$	1·750	$2\frac{7}{8}$ and 3	72 to 76	$2\frac{1}{2}$ to 3

Intermediate diameters have same squares as sizes below.

The heads of fluted hand reamers have same size squares as Whitworth taps and International thread taps respectively.

The sizes of squares are stated in fractions and in decimals of inches, to facilitate measurement with either the mechanics' rule or the micrometer calliper.

No. of □ may be quoted when ordering tap wrenches.

Cast-Iron Muff Couplings.

Dimensions in Inches.					No. of Bolts.

KEEPING BOLTS IN PLACE IN OPEN-SLOTTED TABLES.

When bolts have to be used for repeat work in drilling machine or other open-slot types of tables, the flopping about and dropping of these bolts becomes a time-wasting nuisance. Fig. 27 shows two methods of holding them firmly in position, so that work can be removed

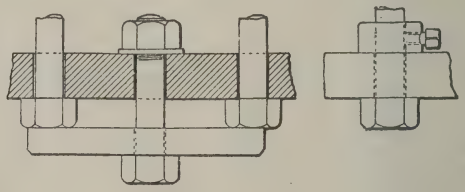

FIG. 27.

and a fresh piece substituted with the minimum of inconvenience. In the one case a clamp is suspended from a bolt and drawn up against the heads ; in the other a loose collar is slipped down the bolt and tightened with a set-screw, an easier way than troubling to thread the bolt right down and putting a nut on. (*'Machinery.'*)

Indicator for Wire Gauge.

A simply made indicator to enclose the notch of a wire gauge that is in use, and save time and trouble when making repeated gaugings, or searching amongst stock or scrap, can be made as

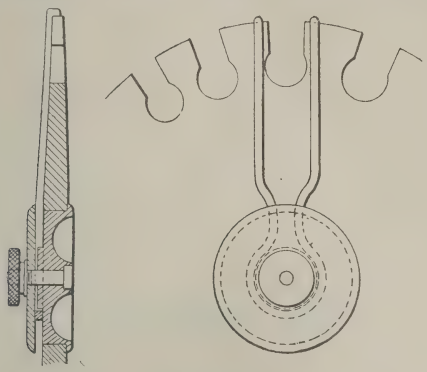

Fig. 28.

shown by fig. 28. The principle is to use springy wire, which may be altered to come just outside the edges of each opening. After holding it at this setting, clamping is done by tightening the knurled nut, which draws the large washer down on the wire and binds it. (*'Machinery.'*)

SECTION XXII

THE ATMOSPHERE – WIND – AIR RESISTANCE – WIND-MILLS–TRANSMISSION OF POWER BY COMPRESSED AIR–AIR COMPRESSORS–PNEUMATIC DESPATCH TUBES

(With Contributions by Edward Butler, M.I.Mech.E., R. A. Sturgeon, A.M.I.C.E., and R. Myles Hook.)

SECTION XXII

THE ATMOSPHERE—WIND—AIR-RESISTANCE—WINDMILLS—TRANSMISSION OF POWER BY COMPRESSED AIR—AIR COMPRESSORS—PNEUMATIC DESPATCH TUBES.

THE ATMOSPHERE.

Air consists, by volume, of oxygen 20·84 parts, of nitrogen 79·16 parts; and by weight, of oxygen 23·15 parts, and of nitrogen 76·85 parts. Also ·03 to ·04 per cent., by volume, of carbonic acid.*

One cubic foot of ordinary dry air at normal pressure, temp. 62°F., weighs 532·5 grains (saturated, 529 grains); or 1 lb. of air contains 13·146 cubic feet.

Dry air is 819 times lighter than water. Aqueous vapour, 1·4 per cent. by volume.

The mean weight of a column of air 1 inch square and 45 miles high is 15 lbs.

At 7 miles above the surface of the earth the air is 4 times lighter than at the earth's surface; at 14 miles, 16 times; at 21 miles, 64 times. Total weight of atmosphere, 5,300 billion tons.

According to a writer in *Nature*, the result of experiments made with forty balloons (sent up in Great Britain) has been that the isothermal layer was reached more than thirty times. Its average height was 35,000 ft. (10·7 kilomes.); it is rather higher with a high barometer. The mean temperature found was −53·6°F. (−77°C.), considerably higher than the Continental mean. The extremes observed in England were −22°F., near Ditcham Park, Hants, on July 24, and −78°F., near Oxford, on September 12, 1907. On the same day, November 11, 1907, the temperature was −42°F. at Ditcham at 36,000 ft. altitude, −58°F. in Oxfordshire at 38,500 ft., and −74°F. near Manchester at 37,000 ft. The existence of an isothermal layer in equilibrium in which the fall of temperature suddenly stops, and yet in which such great differences of temperature occur at spots not very far from one another, is difficult to understand, especially considering the low atmospheric pressure at these heights. (See also page 190.)

To consume 1 lb. of coal requires 11½ lbs., or 150 cubic feet, of air to combine with it.

It is practically impossible to construct an air-engine of any great power, as air, like all other gases, expands but one volume for each 493° of temperature through which it is raised; and, in order to double its volume, we must raise it 493° more, that is to 986°F., which is much too high for practical purposes. Even if air could be worked at this temperature, it would be necessary to have a feed-pump of nearly the capacity of the engine, and the engine itself would have to be more than twice the size of a steam-engine of the same power.

The expansion of air, like all other elastic fluids, is uniform at all temperatures.

If h = height of barometrical column of mercury; K = number of square inches in section of tube; 13,568 ozs., or 848 lbs. = weight of cubic foot of mercury at mean temperature; p = number of pounds pressure of air on square inch of surface; then

Pressure of atmosphere on K sq. ins. $= p \times K$. Weight of column of mercury $= \frac{K h}{1728} \times 848$.

But column of mercury balances the pressure of the atmosphere; therefore

$$p \times K = \frac{K h}{1728} \times 848, \quad \text{or,} \quad p = \frac{848}{1728} \times h = \frac{53h}{108} = \frac{h}{2} \text{ very nearly.}$$

Hence it appears that *the pressure of the atmosphere in pounds per square inch is very nearly equal to half the column of mercury in the barometer-tube in inches.*

* Air contains 15 parts of 'neon,' and 5 parts of 'helium,' in one million volumes (*Dewar*).

INCREASE OF BULK OF AIR BY INCREASE OF TEMPERATURE.

The column of mercury in the barometer in this country varies from 28 to 31 ins.; therefore the mean column is 29·5 ins.; and by the foregoing result the mean pressure of the atmosphere will be about 14·7 lbs. per square inch. The altitude or head of the atmosphere at uniform density will be that of a column of water 33·95 ft. high divided by the specific gravity of air (·0012046), or 28,183 ft. The velocity due at the foot of this head will be: $V = 8·02\sqrt{28183} = 1346·4$ ft. per second, the velocity at which the air will pass into a vacuum. The motions and effects of gases by the force of gravity are precisely the same as those of liquids. Under like conditions a conduit will discharge 30·55 times more air than water.

Rankine assumes a standard English atmosphere to be 14·704 lbs. per square inch in the latitude of London, or equal to a mercury column 29·922 ins. high at 32° F., which = 30 ins. at 57·8° F.

The metrical atmosphere, 760 mm. (29·922 ins.), at 0° C. (32° F.) = 1·0333 kilograms per square cm., or 14·6967 lbs. per square inch, at Paris, = 14·686 lbs. at New York.

To find the barometric height, H, at any other latitude, l,

$$H = 760 \times \frac{(1 + ·00531 \sin^2 48° 50')}{(1 + ·00531 \sin^2 l)} \text{ mm.},$$

where 48° 50′ is the latitude of Paris.

LIQUID AIR.

Liquid air is made by successively compressing and cooling air in a triple effect series, or more the last effect being intensified by cooling the compressed air by the expansion of a portion that is allowed to escape.

The critical temperature of liquid air, above which it cannot be liquefied, is: —90° C. (170° C. absolute), and the corresponding critical pressure is about 40 atmospheres. Its temperature at atmospheric pressure is: —191·4° C. = —312·6° F., and its colour is a light blue. Its density at —191·4° C. is 0·933 (water being 1·000), and its specific heat is 0·50.

Left to stand, liquid air loses some of its nitrogen, which evaporates at a lower temperature than oxygen.

There is not much opening for liquid air as a motive power. One pound of it stores 139,100 foot-pounds of work; whereas a pound of paraffin oil contains over 15,000,000 foot-pounds, of which 10 to 30 per cent. can be converted to power. The uses of liquid air are special. It will purify chloroform, alcohol, and ether by the elimination of impurities in the process of crystallisation, and may be used to purify ether anæsthetics, and chemicals.

Liquid air from which part of the nitrogen has evaporated will render explosive cotton, felt, powdered charcoal, and similar combustibles, because of the great amount of available oxygen brought to bear on the combustion. Powdered charcoal made into paste with the partly evaporated air is used for blasting, being rapidly filled into the shot holes and detonated. If a shot should miss fire it becomes automatically safe by evaporation in half an hour.

Liquid air can be carried in double cased tin vessels lined between with hair felt to keep out the heat. It may have useful therapeutic effects.

As much power is needed to compress air, and liquefy it, as it can possibly give back when boiled off again by heat from the atmosphere or other source. Liquid air if partly rid of its surplus nitrogen would form a useful source of impure oxygen for intense combustion in the laboratory, or special work.

When liquid air is used as a motive power it cannot give more power than that represented in the reverse operation of compression, and can only give power by receiving heat from an external source to supply that latent heat which it lost when liquefied. Liquid air in fact behaves exactly as water behaves, only it can receive its latent heat several hundred degrees below the point at which water receives it.

AIR VELOCITY AND PRESSURE.

Velocity of Air.

When air passes into an air of less density, the velocity of its passage is measured by the difference of the densities of the two.

H and h = densities of the air in inches of mercury; t = temperature (F.°) at the time of passage; and V = velocity of air in feet per second.

$$V = 1347{\cdot}4 \sqrt{\frac{H - h}{h}\left(1 + 0{\cdot}002088t\right)}.$$

Pressure against a Plane Surface moved through the Air.

P = pressure against plane. a = area of plane, in square feet. v = velocity, in feet per second.
v_1 = velocity in miles per hour.

$$P = {\cdot}00142av^2 \text{ lbs.}^* \qquad P = {\cdot}0029av_1^2 \text{ lbs.}^*$$

$P = ({\cdot}003 + {\cdot}00004q)\, av_1^2$ lbs.,† where q = ratio of sides of rectangular plate.

The quantity ·003 decreases as v_1 increases, being ·0029 for 90 miles, and ·0032 for 0 to 25 miles.

Horse-power required to move a Plane Surface against the Air.

H.P. = horse-power. a = area of plane, in square feet. v = velocity, in feet per minute.

$$H.P. = {\cdot}000,000,000,010,6av^3.$$

TABLE SHOWING HORSE-POWER CONSUMED IN MOVING A PLANE SURFACE AGAINST THE AIR.

Speed in		H.P. per Sq.Ft. of Effective Surface.	Speed in		H.P. per Sq. Ft. of Effective Surface.
Miles per Hour.	Feet per Min.		Miles per Hour.	Feet per Min.	
10	880	0·00722	50	4,400	0·903
15	1,320	0·0244	75	6,600	3·05
20	1,760	0·0514	100	8,800	7·23
25	2,200	0·110	150	13,200	24·4
30	2,640	0·195	200	17,600	57·8

As a result of tests, M. Eiffel found that, for velocities of from 60 ft. to 130 ft. per second, the resistance offered by air to a moving surface is practically proportional to the square of the velocity, although the exponent increases slightly and gradually when velocities exceeding 100 ft. per second are employed. The resistance or pressure in pounds, P, is represented by the product KSV^2, where K is a constant depending on the size and shape of the surface tested; S is the area of the surface in square feet, and V is the velocity in miles per hour. At ordinary temperatures and a barometric pressure of 760 mm., M. Eiffel found that the value of the coefficient K ranged from 0·00286 to 0·00327, the latter value being apparently a maximum attained only with large surfaces. Thus, for a circular surface of 1 sq. ft., the value of K was 0·00286, for a square surface of the same area 0·00295, and for an area of 10 sq. ft. 0·00323. He also found that the resistance of an inclined surface is practically the same as that of a normal one, when the perpendicular to the surface makes an angle less than 30° with the direction of motion. For greater angles the resistance proportionately decreases (zero at 90°). On pressure boards ranging from 25 sq. ft. to 100 sq. ft. in area, which were mounted at the top of a 50 ft. tower, Dr. T. E. Stanton found, from a large number of experiments, that the mean value of this constant was 0·0032.

Dr. Hutton deduced that the resistance of air varied as the square of the velocity nearly, and to an inclined surface as the 1·84 power of the sine × cosine.

The figure of a plane makes no appreciable difference in the resistance, but the convex surface of a hemisphere, with a surface double the base, has only half the resistance.

At high velocities the resistance becomes nearly a constant quantity.

The resistance of the air to a train of cars in a dead calm was found to be $\frac{1}{350}$ of their weight.

The velocity of a train of cars which gave a resistance of $\frac{1}{256}$ of the load with a fair wind was 34½ miles per hour, and only 27½ with an adverse wind.

* T. E. Stanton, National Physical Laboratory. † Hagen.

Flow of Air.

Weight of Air Passing Through a Nozzle.

The weight of air at atmospheric pressure passing through a properly-designed nozzle into any vacuum of not less than 8 lbs. may be calculated as follows (Leblanc) :—

W = lb. weight per hour ; A = area of nozzle neck in square inches ; T = atmospheric temperature in deg. Cent.

$$W = \frac{20330A}{\sqrt{T+273}}.$$

Air Friction.

Recent experiments on the flow of air through smooth sheet steel ducts varying in size from 12 ins. to 48 ins. in diameter, at velocities ranging from 1,000 ft. to 2,400 ft. per min., appear to show that the average value of the coefficient of friction is 0·0035.

WIND.

Impulse of Wind.

V = velocity of wind. D = direct impulse in pounds on one square foot.

$D = V^2 \times \cdot00271$, where V is in miles per hour
$D = V^2 \times \cdot00312$, where V is in knots per hour } *

Wind Velocity by Robinson Anemometer.

If

v = velocity of anemometer cups in miles per hour ; V = velocity of wind in miles per hour ;

then, $V = 2v + 4$.

Instrument fails to record velocities below 4 miles per hour.

(*W. H. Dines*, 'Report of Astronomer Royal, 1921.')

* Recent researches have shown that the constants ·00271 and ·00312 are apparently too small by about 6 per cent.

WINDMILLS.

(Contributed by Edward Butler, M.I.Mech.E.)

The driving shaft of a windmill situated on level ground should, with a tower of moderate height, be tilted *upwards* at an angle of 6° to 8°. If on a low hill with the fall against the prevailing wind the shaft is better horizontal, but when situated on a steep hill the best result will be obtained by tilting the shaft *downwards* a few degrees.

The shaft should be mounted so that the driving-wheel faces the wind in either direction, and at a height ranging from 20-25 ft. on high ground, and 50-70 ft. on low ground, and so that it is clear of buildings or trees.

The tower should, in ordinary circumstances, be of sufficient strength to hold up against a 40-mile storm with a wind pressure of 8 lbs. per sq. ft. On exposed elevations subject to wind velocities exceeding this, a windmill unless specially constructed is not suitable.

WIND ACTION.

Velocity per hour in miles.	Pressure per sq. ft. in lbs.	Description of Wind.	Action on Windmill.
5	0·125	Faint breeze . .	Will not drive.
8	0·33	Breeze . . .	Will start against light load.
10	0·5	Fresh breeze . .	Will run slowly.
15	1·125	Good wind . .	Will run steadily.
20	2·	Strong wind . .	Gives best service.
25	3·125	Very strong wind .	Maximum useful effect.
30	4·5	Gale . . .	Should be partly furled or held out of the wind.
40	8·	Storm . . .	Must be totally put out of action.
60	18·	Violent storm .	Not safe.

Power of Windwheels.

The total momentum of wind is,

$$\frac{0{\cdot}08}{32} \times \text{area} \times \text{velocity}^2 = 0{\cdot}0023\ AV^2 \text{ approximately}$$

The turning moment at starting, for each vane, equals

$$0{\cdot}002\ AV^2 \cos\theta r,$$

and when in motion is

$$0{\cdot}0015\ AV^2 \cos\theta r \text{ for moderate speed,}$$

the constant ·0015 decreasing to ·0012 with increase of speed;

where A = area of vane; V = velocity of wind; $\cos\theta$ = angle to the axis of rotation; r = mean radius; 0·08 is the mean weight of one cubic foot of air. Velocity in ft. per sec. is to miles per hour as 22 is to 15.

HORSE-POWER OF WINDWHEELS.

Shaft or b.h.p. of a 4-armed wheel with cloth sails

$$= \frac{v^2 r^2}{512477}\ (\textit{Rankine}), \quad \frac{4\ Av^2}{1145833}\ (\textit{Weisbach}).$$

The brake h.p. of a multi-vaned wheel

$$= \frac{0{\cdot}6 \times 0{\cdot}78\ (D^2 - d^2) \times V^2}{33000};$$

where A = area of one vane; D = total diameter of wheel; d = clearance diameter at centre; r = radius of sail tips; V = velocity in feet per second.

A windwheel (Dutch pattern) with four cloth sails, each 24 ft. in length and 6 ft. in breadth, will develop 4-5 b.h.p. in a 20-mile wind.

Windwheels with multiple vanes have a considerable advantage in starting with low velocity winds and in slow running.

The power of a windwheel is not so great as is popularly supposed. A 16 ft. wheel, for instance, with multiple cambered steel vanes, only develops about 1 b.h.p. in a 15-mile wind, and this is reduced to less than one-half in a 10-mile wind, although increased to nearly double in a 20-mile wind.

Constructional Remarks.

According to windmill practice (old type) the wheel may have 4, 5, or 6 cloth sails of rectangular form, the length being equal to five times the breadth; but the total surface should not exceed one-third of the whole surface described by the radial arms carrying the sails. The angles of the cross bars for supporting the sails, which commence at one-seventh from the wheel centre, are usually 24°, 21°, 18°, 9°, 3°, from the plane of motion.

While more power can be gained by increasing the sail surface to more than one-half the whee area, the difficulty is such with the old practice of using cloth sails that the sail area seldom exceeds one-third and is more often reduced to one-fourth.

The angles of the sails to the plane of motion, according to Smeaton, should be 20°, 19°, 18°, 16°, 12½°, 7°; and again, to Forrester, as 24°, 21°, 18°, 14°, 9°, 3°.

In multi-vane windwheels, the vanes—either oil-soaked wood slats, or cambered steel plates of light construction and galvanised—are carried by a series of 6-8 steel or wooden arms, fixed to a steel boss. The arms are braced to an extension of the wheel boss by tension rods. The vanes are fastened to two sets of cross-bars, connecting the arms together, in sections of 8 to 15, according to wheel diameter and angle to the plane of motion; this varies from 20° to 40°, but is generally 25° in flat or cambered vanes of uniform angle. The steeper the angle the narrower the vanes, to reduce whirl resistance. For direct connected pumps the angle is steeper than for geared down pumps. Steel vanes are cambered more for rigidity than for any increased driving efficiency. There is some advantage in forming the angle to suit the radius, but is not of such consequence as with wide cloth sails. What is of more importance is for the shaft to run in well lubricated roller bearings and for the turntable to move freely so that the wheel shall be held square to a light wind.

Power Control.

In windwheels with wide cloth sails, these are furled to suit either the load or the wind. In wheels with multiple vanes the usual practice is to fit a governor-vane on one side, at a right-angle to the wheel shaft, and for the tail-vane to be swivelled to the turntable, and to be held end-on either by a spring or a weight, or, better still, by a series of weights chained together. These weights should be proportioned for the governor-vane so as to pull the turntable, and the wheel with it, partly out of the wind as soon as the velocity increases 20-25 m.p.h., and to bring round the wheel edge-on to the wind in a storm.

Wind Pumps.

The popularity of wind-driven pumps is due to the introduction of the multiple-vaned wheel and to automatic governing, in combination with light easily-erected steel towers, the average power developed ranging from 1 to 6 shaft h.p., with a wind velocity of 15 m.p.h. (22 ft. per sec.), a 20-mile wind nearly doubling this power, and a 10-mile wind generating about half the power obtained by a 15-mile wind.

In ordinary practice the pumping capacity of a wind engine, as expressed in pounds of water raised per minute by pressure-head in feet, rarely exceeds from 25 to 35 per cent. of the wheel h.p., but is influenced by wheel diameter, the angle of the vanes, and the method of transmitting the power to the plunger.

In geared-down transmissions, the wheel-shaft pinion should be situated at the side of the pump wheel, and not above or below it. This disposition reduces friction and maintains correct alignment and mesh of the cogs.

Owing to the very inadequate fly-wheel effect of a windwheel, it works at considerable disadvantage in driving single-acting pumps direct, and only less so when geared down; double-acting, or better, 3-throw single-acting pumps, oppose a more equable torque, but are impracticable for small installations. For this reason a rack or mangle transmission is peculiarly applicable to a wind-driven pump, as shown in the higher duty and efficiency in the table below.

The location of a wind pump is generally influenced more by the available water supply than from any consideration of available wind-power, the tower usually being constructed high enough—50 to 70 ft.—to clear all obstacles around for a distance of 300 to 400 ft. Under normal conditions eight hours' pumping only can generally be relied upon as a daily average; so that to make an installation successful a storage-tank or reservoir should be provided, the minimum capacity of which may with advantage equal from four to seven days' pumping, although a larger reserve is often allowed for.

AIR COMPRESSION.

If

p = actual pressure of air in a container;
P = gauge „ „ „
v = volume of air at pressure p;
p_1 = actual pressure of air when compressed;
P_1 = gauge „ „ „
v_1 = volume of air when compressed;

then,

$$\frac{p}{p_1} = \frac{P + 14{\cdot}7}{P_1 + 14{\cdot}7} = \frac{v_1}{v},$$

the compressed air being *at the same temperature* as the air before compression—that is to say, if the heat due to the compression is allowed to become dissipated.

If the air is compressed from atmospheric pressure (i.e. if gauge pressure P = 0), then

$$\frac{14{\cdot}7}{P_1 + 14{\cdot}7} = \frac{v_1}{v},$$

or,

$$P_1 = 14{\cdot}7\frac{v - v_1}{v_1}, \qquad \text{and} \qquad v_1 = v\frac{14{\cdot}7}{P_1 + 14{\cdot}7}.$$

Example 1.—What gauge pressure (P_1) would be required to reduce 5 cub. ft. (v) of air at atmospheric pressure down to 3 cub. ft. (v_1), at the same temperature?

$$P_1 = 14{\cdot}7\,\frac{5-3}{3} = 9{\cdot}80 \text{ lbs.}$$

Example 2.—What volume (v_1) will 1 cub. ft. of air occupy when compressed to 30 lbs. gauge pressure (P_1), at the same temperature?

$$v_1 = 1\,\frac{14{\cdot}7}{30 + 14{\cdot}7} = {\cdot}329 \text{ cub. ft.}$$

If the heat is not allowed to disappear when the air is compressed, then

$$\frac{14{\cdot}7}{P_1 + 14{\cdot}7} = \left(\frac{v_1}{v}\right)^{1{\cdot}408}$$

or,

$$P_1 = 14{\cdot}7\frac{v^{1{\cdot}408} - v_1^{1{\cdot}408}}{v_1^{1{\cdot}408}}, \qquad \text{and} \qquad v_1 = v\left(\frac{14{\cdot}7}{P_1 + 14{\cdot}7}\right)^{{\cdot}7102}$$

If $P_1 = 30$, as in the case of *Example* 2, then the value of v_1 instead of being ·329, will be

$$({\cdot}329)^{{\cdot}7102} = {\cdot}454 \text{ cub. ft.}$$

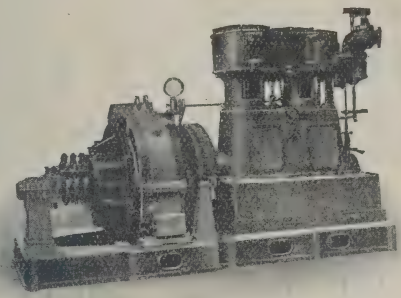
AIR COMPRESSORS.

Power required to Drive Air Compressors.

The power required to drive air compressors is based on adiabatic compression of the air during each stage. It is assumed that the mechanical efficiency is 60 per cent. at 5 pounds per square inch, increasing to 80 per cent. at 40 pounds per square inch and above. It is quite usual for the best makes to attain an efficiency exceeding 90 per cent., but for general purposes it is wiser to assume the lower figure. In the case of machines of small output and low pressure, the efficiency is frequently below 50 per cent. Hence, for compressors dealing with much less than 100 cubic feet per minute, it is advisable to allow a greater horse-power than would be obtained by working to the table.

In providing a driving unit for an air compressor, the type of machine should be considered before fixing the size of the driver. Thus, the turning effort required by a single-acting, single-cylinder air compressor may vary considerably above and below the mean, and allowance must be made for this, particularly in the case of direct-coupled drives.

Horse-Power to Compress Air.



$$\left.\begin{array}{l}\text{Horse-power to compress}\\ \text{100 cu. ft. of free air per min.}\end{array}\right\} = 1{\cdot}88\ np\left\{\left(\frac{p_1}{p}\right)^{\frac{{\cdot}29}{n}} - 1\right\};$$

where,

p = initial pressure in lbs. per sq. in. (assumed at 14·7 lbs. per sq. in.);

p_1 = final pressure in lbs. per sq. in. = gauge pressure + 14·7;

n = number of stages of compression.

(R. A. Sturgeon.)

DESIGN OF AIR COMPRESSORS.

The best practice adopted in the design of air compressors is as follows:—The maximum terminal pressures are, for one stage, 80 lbs. to 100 lbs. per sq. in.; two stages, 600 lbs. per sq. in.; three stages, 1,500 lbs. per sq. in.; four stages, 2,500 lbs. to 3,000 lbs. per sq. in.; five stages, 4,500 lbs. per sq. in.; and above 4,500 lbs. per sq. in., six or seven stages to 6,000 lbs. per sq. in., which is about the highest pressure for which an air compressor has been constructed. In the case of very small machines these pressures, for a given number of stages, are often exceeded in order to reduce complication. For example, machines have been constructed and work quite satisfactorily when compressing to 2,500 lbs. per sq. in. in two stages. The temperatures attained, however, make it necessary to carry out the cylinder lubrication by soapy water.

(J. M. Ford, in a paper read before the Greenock Association of Shipbuilders and Engineers.)

BROTHERHOOD AIR COMPRESSORS FOR MODERATE PRESSURES.

(Peter Brotherhood, Ltd., Peterborough.)

These compressors are made in two general classes, the first being of the single-acting type with trunk pistons, employed where a small output and an inexpensive machine is required, and lubricated automatically. The second embodies a wide range of forced lubrication double-acting compressors, for one or two stages, and capacities up to 5,000 cub. ft. of free air per minute.

The valves (which are a source of trouble in air compressors) are of the Brotherhood Mesta type, fig. 1, which combines small lift and light weight with corresponding avoidance of hammering and wear of seats; they will operate at speed up to 700 revs. per minute without noise or wear, and reduce wire drawing to a minimum. They are fitted in both single and double-acting machines.

The general construction of the double-acting compressors is shown in fig. 2, which illustrates a two-stage steam-driven machine of 600 cub. ft. capacity. The design follows generally that of the Brotherhood high-speed engines, forced lubrication being supplied at high pressure to all bearing surfaces, by a valveless pump.

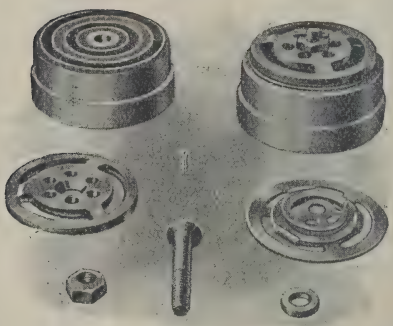

FIG. 1.

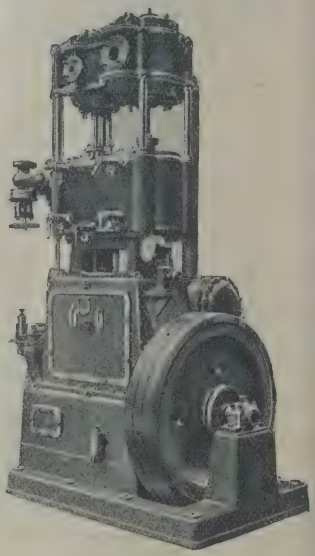

FIG. 2.

The governing combines control of the air intake and of steam admission, thereby regulating the output of the compressor exactly to requirements.

Intercooling in the two-stage types is effected by a straight tube intercooler, easily accessible for cleaning.

For belt or motor-driven compressors a constant speed form of governor is employed, allowing the machine to run without load when the pressure in the reservoir reaches its required point.

The double-acting compressors are of single and two-crank types: the former for motor or belt-driving, either simple or tandem compound, and for steam driving, either simple or annulus compound; in the latter, two-cylinder simple or compound is used for either steam, belt, or motor driving.

BROTHERHOOD HIGH-PRESSURE COMPRESSORS FOR AIR OR GAS.

(Peter Brotherhood, Ltd., Peterborough.)

Air and gas storage, liquifying, etc., demand pressures higher than are possible with compressors of ordinary design. Brotherhood high-pressure compressors are made for multi-stage working, and are designed to meet the widely-varying requirements met with in high-pressure work.

Two examples are illustrated. Fig. 3 shows a three-stage belt-driven oxygen compressor of a capacity of 3,500 cub. ft. per hour, and compressing to 250 atmospheres. The compressing cylinders and intercooling coils are carried in an open water tank, and all valves and plungers are removable without breaking pipe connections.

F. 1079

The cylinders and low-pressure plungers are made of bronze, and the high-pressure plunger of special rustless alloy which acquires a glass-like surface in working.

The packings are of segmental metallic type of special design, superseding the fibre and other soft packings which cause so much trouble by friction and wear.

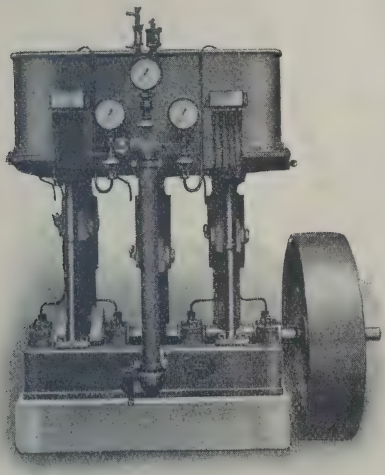

FIG. 3.

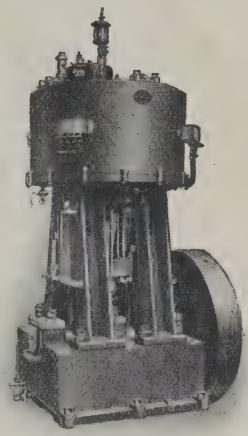

FIG. 4.

The internal lubrication of these high-pressure compressors can be widely varied to suit requirements of gases of various types ; water without other lubrication can be used where necessary.

Fig. 4 shows a compressor made for working to a pressure of 400 atmospheres, about 2½ tons per sq. in. Six stages of compression are employed, the barrels with the intercooling coils being in a closed tank, as shown. This is probably the highest pressure of air attained in a machine of considerable capacity and capable of running for extended periods.

THE 'FULLERTON' PATENT AIR COMPRESSOR.

(Fullerton, Hodgart & Barclay Ltd., Vulcan Works, Paisley.)

In this compressor the lower crank case, upper crank case, and crosshead guides and soleplate are all constructed from the point of view of rigidity.

The trunk guides being cast in one piece with the distance piece, and the top part of the latter forming the bottom cover for the cylinder, ensures the perfect alignment throughout the whole working parts. The distance piece is so arranged that the rod in contact with the crank chamber never comes into contact with the cylinder gland, therefore avoiding oil being carried into the cylinder from the piston rods. Large openings are provided to enable the packing glands and wyper glands to be easily accessible

A vertical tubular intercooler is fitted behind the air compressor. The tubes and baffle plates are so arranged that the most effective use of the cooling surface may be obtained. The tubes are arranged so that in the event of damage they can be removed in a minimum of time.

The air cylinders are constructed of a special mixture of hard close-grained cast iron, water jackets being embodied in the walls of the cylinder for the cooling water, which also passes through the end cover jackets.

WESTINGHOUSE THREE-STAGE AIR COMPRESSOR.

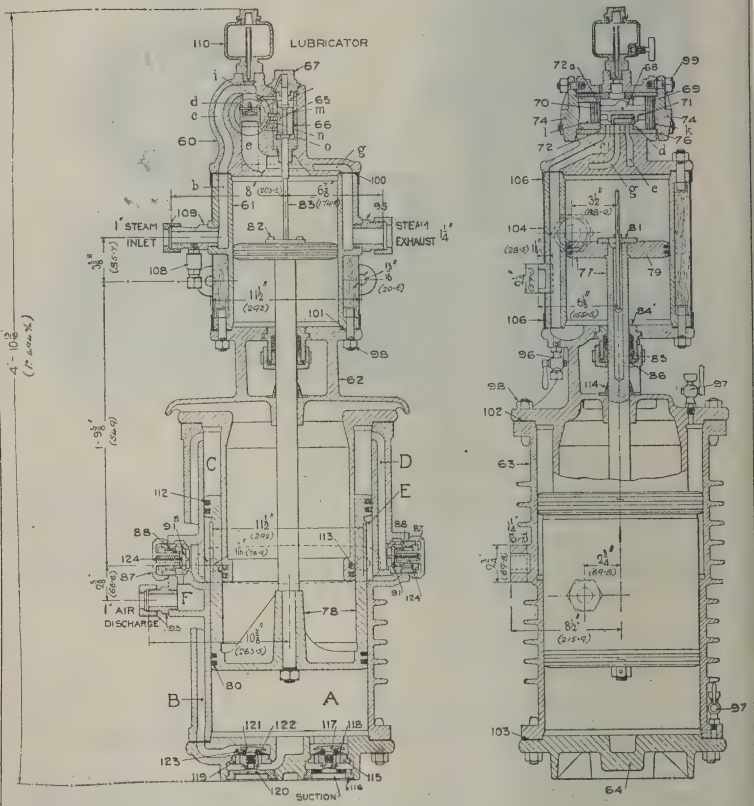

FIG. 5.

A special feature is the type of valve employed. These are of a patent strip plate type, and are rectangular in form. The plates are made of special tough steel having a very high elastic limit. The valve is such that for a given port area the absolute minimum weight of valve possible is obtained, there being no metal in the valve other than that required to cover the port. Each valve weighs only about 1 oz. Owing to its shape it is possible to obtain the maximum of port area in minimum space, which allows the valves being placed against the cylinder walls and so dispensing with large valve ports, thus giving an attendant gain in efficiency. The inlet valves are on the opposite side of the cylinder to the outlet valves, thus obviating the incoming air having to pass through the heated walls of the port before admission to the cylinder.

Owing to the arrangement of the valves on the cylinder walls, the valve chest covers giving access to the valves are of very small dimensions, so that they can be handled by one man. A valve can be inspected and replaced in half an hour.

Forced lubrication supplied by a valveless pump worked from the eccentric of the crankshaft is fitted for the lubrication of all the reciprocating parts, namely, main bearings, crank pins, crosshead pins, etc. The oil is collected in the bottom of the crank casing and taken through an oil strainer back into the oil pump and used over again. Very little lubricant is required on the air cylinders, and a drop sight feed lubricator is fitted on the H.P. and L.P. cylinders. This has been found by practice to be quite sufficient for the air cylinders.

Westinghouse Air Compressors.

The valve motion of the Westinghouse type of steam-driven air compressor is simple and compact, being entirely in the tophead, and all its parts are so arranged as to readily permit of examination or replacement. Should repairs to the valve mechanism be necessary, the tophead can be quickly removed and replaced by another, so that no unnecessary delay need occur through the pump being out of service, pending repair. The air valves are contained in separate cases, so placed that they can readily be taken out.

The pumps are arranged vertically, and consist of a steam cylinder connected by a centre-piece to an air cylinder, or air cylinders, for either simple, compound, or three-stage compression. The three-stage compressor (fig. 5, p. 1080) is so constructed that air for compression is inhaled only on the upstroke of the piston, whilst on the downward stroke air at atmospheric pressure is drawn into and circulates around the inner walls of the cylinder and piston, to be again expelled on the succeeding upstroke; thus a supply of cool air is drawn into the interior of the pump at every alternate stroke, and the pump is air-cooled internally as well as externally; the result being that air compressed up to 300 lbs. per square inch is delivered at a temperature not exceeding 266°F., rendering the employment of water-cooling jackets unnecessary with this type of compressor.

For service on electric railways, the Westinghouse Brake & Saxby Signal Co., Ltd., manufacture an air compressor driven direct by special slow-speed electric motor, and for industrial purposes a similar type of compressor for operation by either electricity or belt.

Belliss High-speed Forced-lubricated Compressor.

(Belliss & Morcom Ltd., Birmingham.)

This type of compressor, fig. 6, page 1082, embodies the best features of the Belliss engine, including the system of forced lubrication originated by the firm in 1890 (see Section XXIX, Part IV). The working parts are generally the same as those of the 'C' type engine, Section XXIX, Part IV. The air cylinders are water-jacketed and two-stage, as desirable for pressures in excess of 60 lbs. per sq. in., except in the case of quite small compressors.

The compressor shown is adapted for being directly connected to an electric motor or for rope or belt driving. When operated at constant speed the air supply is controlled by an automatic valve on the inlet as shown, the valve being of the equilibrium double-beat type and controlled by an air relay, so designed that on the air pressure exceeding the intended pressure by 3 to 5 per cent. the air supply is cut off entirely, the pistons running *in vacuo* until the demand again causes the pressure to fall. As the air supply is not throttled the system is a highly efficient one. Special tests have demonstrated that the power required to run the compressor light may be only 6 per cent. of the full power, and under 9 per cent. for the compressor and motor combined.

One of the chief points in the design of these compressors is the air valves. These are of the Rogler-Hoerbiger patent thin plate type (fig. 7, page 1082), devised as the result of experience gained

during the construction of the Simplon Tunnel, and which have come to be recognised as one of the best types of valves for air compressors. The valves consist of light discs of tempered steel, perforated to give a multiple opening and falling on a cast-iron grid with suitable cushion and guard plates above. These valves are very reliable, noiseless in action, and a minimum amount of power is lost in operating them.

The Bellis compressors are also made with self-contained steam cylinders, controlled by the makers' patent relay type air governor, designed to vary the speed of the compressor in accordance with the demand for air, there being also a centrifugal governor directly connected to the crankshaft to prevent the speed under any conditions exceeding a predetermined maximum.

Air-Compressor Lubrication.

An oil suitable for air-compressors should always be highly filtered, because such oil will have a minimum tendency to form carbon deposits. Oil compounded with vegetable or animal oils are quite unsuitable for air cylinders.

Use only a straight-run, highly filtered, pure mineral oil of the lowest natural flash test consistent with the viscosity necessary to lubricate the cylinders and provide a proper piston seal.

The correct viscosities (worked out by the members of the Compressed Air Society, U.S.A., all of whom are builders of air-compressors) are given in the following tables, showing the proper specifications for both paraffin and asphaltic oils of various viscosities.

Physical Tests of Paraffin-base Oils.

(W. F. Osborne, 'Power.')

VACUUM PUMPS.

The Bailey Patent Slide Valve 'Dry' Vacuum Pump.

In the 'K' Vacuum Pump (*W. H. Bailey & Co. Ltd., Manchester*), the slide-valve is without a stuffing-box, and the spring delivery valve is not carried by the slide-valve but works vertically on a stationary seat, easily accessible even when the machine is running. By this arrangement the slide-valve does not run in the interior of the valve chest, but on the outside of it, and is consequently, easy to fit and adjust; it has no stuffing-box to its spindle.

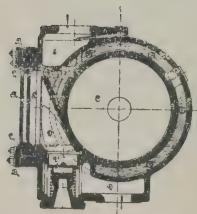

Fig. 8.

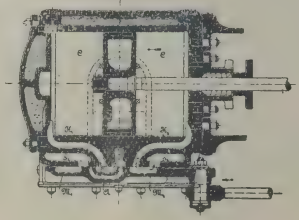

Fig. 9.

Fig. 8 shows a transverse section, and fig. 9 a longitudinal section of the standard air cylinder of the 'K' pump. The cylinder and back covers are water-jacketed, the front cover is cast in one with the cylinder and a joint between the cylinder and the frame is avoided. In the larger sizes the front cover is water-jacketed.

The action of the valve is as follows:—

The air or gases enter by the suction pipe S and pass to the spaces S1 and S2. In fig. 9 the piston is passing towards the left-hand side and draws air into the cylinder from S2 through the space M2 and the port K2. At the same time it discharges the air drawn in during the preceding stroke by K1, P, and D, the slide-valve being set in relation to the crank so that the spaces S1 or S2 and D are put into communication at the right moment with the corresponding ends of the cylinder. Besides the ports M1 and M2, through which the gases pass into the cylinder, and the port P1 through which they are discharged, the slide-valve has a compensating or equalising port A which communicates between the discharge side of the piston and the suction side, thus equalising the pressure. When the piston has reached the dead point this port opens, for an instant of time, the communication between the two sides of the piston, the cylinder being cut off from the inlet and outlet by the slide-valve. The tension or pressure in the clearance space is thus reduced almost to the suction tension or pressure, and the piston can now draw air in much sooner, the effective suction stroke or volumetric efficiency being thereby increased. In addition to the slide-valve there is a spring valve V. The slide-valve governs the beginning and the end of both suction and discharge strokes. The spring valve has no effect on the volumetric efficiency of the pump, as without it the same volume would be drawn in, but it is necessary in order to reduce the power required to drive to the lowest possible limit. The slide-valve opens the suction and discharge at the beginning of each stroke and closes at the dead point, so that the pump can be used for any degree of vacuum. The opening of the discharge port at a time when the air or gases are not yet compressed to atmospheric pressure would permit the air in the discharge pipe to flow back into the cylinder, causing back pressure and loss of power. The spring valve prevents this, as it separates the external air from the cylinder and prevents it from entering the cylinder when the slide-valve opens the discharge. When the air or gases in the cylinder are compressed to atmospheric pressure the spring valve opens automatically and the discharge commences. The influence of the spring valve therefore

PARIS, SYDNEY, MELBOURNE, BRISBANE, ADELAIDE, PERTH, WELLINGTON, JOHANNESBURG.

only affects the power for driving as previously stated; it works vertically, is always accessible even when the machine is running, and is noiseless.

The single type pumps will maintain a vacuum of over 29·8 ins. of mercury when exhausting from a closed vessel. When a higher vacuum is necessary, the Bailey Double Vacuum Pump is recommended. This pump will maintain a vacuum of over 29·95 ins. of mercury at normal temperature and with a barometric pressure of 30 ins.

These pumps are particularly suitable as air pumps for condensers for steam engines, central condensation plants, cooling towers, condensers for evaporating plants, vacuum drying plants, distillers, filtering plants, etc.

PNEUMATIC DESPATCH TUBES.

Tubes.

The tubes used in the Pneumatic Despatch Service (telegrams only) of the British Post Office are 3, 2¼ and 1½ inches in diameter, the 2¼-inch being the size in most general use. The tubes are manufactured in lengths of about 28 feet. The tubes are of lead, and are enclosed in cast-iron pipes for mechanical protection. Each length of lead pipe is laid in a wooden trough as soon as manufactured, so that it may be handled without fear of bending. A tightly fitting polished steel 'mandril,' 1 foot long, and of the exact gauge of the tube, attached to a strong chain, and lubricated with soft soap, is then drawn through the entire length of the tube. This operation insures the tube being smooth, cylindrical, and uniform throughout. The jointing of the lead tubes is effected as follows: Previous to the placing of the tubes in the trench, a strong chain is passed through it, and a polished steel mandril, 6 inches long and slightly less in diameter than the diameter of the tube, is heated and attached to the chain, and pushed half its length into the end of the tube already laid; the new length of tube is then forced over the projecting end of the mandril until the tube ends (which have been previously cut flat) butt perfectly together; a plumber's wipe joint is then made. By this means the tube is made perfectly air tight, and the mandril keeps the surface of the tube under the joint as smooth as at any other part of its length. After the joint has been completed, the mandril is drawn out by the chain attached to it, the next length is drawn on and the process repeated.

Carriers.

The carriers in which the messages are placed consist of a cylindrical tube of gutta-percha covered with felt: a 'skirt' projects beyond the open end of the carrier. The pressure behind causes the skirt to expand until it exactly fits the tube and thus prevents the air leaking past. The front of the carrier is provided with a buffer or piston, formed of several discs of felt, which exactly fits the tube. To prevent the messages getting out of the carrier, the end is closed by an elastic band, which can be stretched sufficiently to allow the messages to be put in.

The length, over all, of a carrier for a 2¼-inch tube is 6¾ inches; the inside measurements of the gutta-percha tube or message holder being—length 4⅞ inches, diameter 1¼ inches. The weight of such a carrier when empty is a little over 3 ounces.

The 3- and 2¼-inch carriers will, on the average, take 65 and 25 messages respectively.

The speed of the carrier may be roughly stated to range from 20 to 30 miles an hour for tubes not exceeding a mile in length.

Working Pressure and Vacuum.

The standard pressure is 10 lbs. per sq. in., and the standard vacuum 6½ lbs. per sq. in

For a given effective pressure, carriers travel most rapidly in pressure tubes when the air supply is *intermittent*, i.e. when the message tube is only connected with the compressed air mains during such times as carriers are actually traversing the tubes. The reason of this is, that the compressed air with which the portion of the tube in front of the carrier is full, and which has to be displaced by the advancing carrier, weighs more than the uncompressed air, and consequently requires a greater amount of power to move it. The difference in the two cases is, however, not great, but the higher the pressure the greater is the difference in speed due to this cause. With 6 lbs. pressure, the carrier takes only 3 per cent. longer time with continuous than with intermittent working, whilst with 14 lbs. pressure it takes nearly 6 per cent. longer time.

In the case of carriers propelled by the exhaustion of the air, if the exhaustion is not commenced until the carrier is inserted at the further end, then the carrier commences to move as soon as the exhaustion at that end reaches a few ounces only, and the full exhaustion effect is not felt until the carrier has been moving for some time. When, however, the exhaustion is continuous the carrier on its insertion practically starts off under the full pressure: hence its speed is greater than in the first case. The continuous system of vacuum working, where one tube

is used for the 'up' traffic (i.e. the traffic from the distant to the central or 'power' station) only, is easily effected, whether the traffic is heavy or light; but the intermittent system for the 'down,' or pressure working, which, as pointed out, gives the greatest speed, cannot always be followed out, as during the busy hours of the day the carriers have to be despatched in such quick succession that the current of air in the tube is practically continuous.

Power Required to Work Tubes.

The actual power required for working *continuously* the tubes at a pressure of 10 lbs. per square inch (the standard pressure) is, theoretically, 3·35 horse-power for a 2¼-inch tube 1 mile long; but in practice 50 per cent. requires to be added to allow for losses from various causes, i.e. the actual horse-power should be 5. With 10 lbs. pressure the time occupied in the transit of a carrier through a tube 1 mile long is 2½ minutes.

In order to neutralise the intermittent action of the pumps, and insure a uniform flow of air, reservoirs or 'containers' are provided. These are arranged to have sufficient capacity to give out a reserve supply when the load on the tubes becomes abnormal, as occasionally happens.

For a given transit time the actual horse-power required is much less in the case of vacuum than in the case of pressure working. Thus, for example, the transit time for 10 lbs. pressure is the same as for 6½ lbs. vacuum, but the horse-power required in the two cases would be as 1·83 to 1. Inasmuch, however, as the tubes cannot practically be worked only by vacuum, the calculations for transit time and horse-power must be based on pressure working. The actual power

necessary must be largely governed by local conditions, and no definite rule can be laid down. The power required to work any tube or number of tubes is usually computed, however, on the estimated traffic in carriers per hour which each tube is required to carry. This figure multiplied into the volume of the tube (*vide* Table I.) and divided by 60 gives the volume of air swept out per minute (if there is a number of tubes the figures are of course aggregated), and this affords the capacity of the pump at the required pressure. From Table II. the horse-power for 1,000 cubic feet per minute at any particular pressure may be ascertained.

PUMPING MACHINERY.

The air compressors used for this system are driven by electric motors, oil, steam, or gas engines, and are provided according to the present standard practice with one or more cylinders arranged to draw from the vacuum container and compress the air thus drawn into the pressure container. Automatically controlled auxiliary valves are interposed in the inlet and delivery mains of the pump. They are controlled pneumatically by means of a by-pass connection with the pressure container in such manner that if (*a*) the pressure in the pressure container is low and the vacuum in the vacuum container high, so that the pump is deprived of air to compress, the auxiliary inlet valve on the vacuum main opens to atmosphere and admits free air for compression until the pressure in the pressure container is restored, when the valve shuts. On the other hand, (*b*) if the vacuum is low and the pressure is high, so that the pump would have to discharge against considerable back pressure the air it exhausts from the vacuum container, the auxiliary valve in the pressure main opens to atmosphere until the vacuum is restored. A non-return valve on the container side of each auxiliary valve prevents the loss of pressure or vacuum whilst either auxiliary is open to atmosphere. This system, besides economising in plant and space, absorbs and utilises certain losses which are inevitable with independent pumping for both services.

TRANSIT TIME.

Table III. enables the transit time for any diameter and length of tube at any pressure to be calculated, and from Table IV. can be ascertained the pressure required to drive a carrier

III.—Tables for calculating Time of Transit of a Carrier through a Tube.

Formula: $t = \cdot00872\sqrt{l^3} \times \frac{1}{\sqrt{P}} \times \frac{1}{\sqrt{d}} = A \times B \times C$ secs.

$A = \cdot00872\sqrt{l^3}$.

Example : Required, the pressure, P, to drive a carrier through a tube 5 ins. in diameter (C_1) and 2,000 yds. long (A_1) in 200 secs. (B_1). $P = 608{,}000 \times \cdot 0000250 \times \cdot 200 = 3$ lbs.

through any tube in any time. The chart, fig. 10, based on Table III., shows the Transit Time variation for different lengths of tubes of three sizes, $1\frac{1}{2}$ in., $2\frac{1}{4}$ ins., and 3 ins., each worked at 10 lbs. pressure.

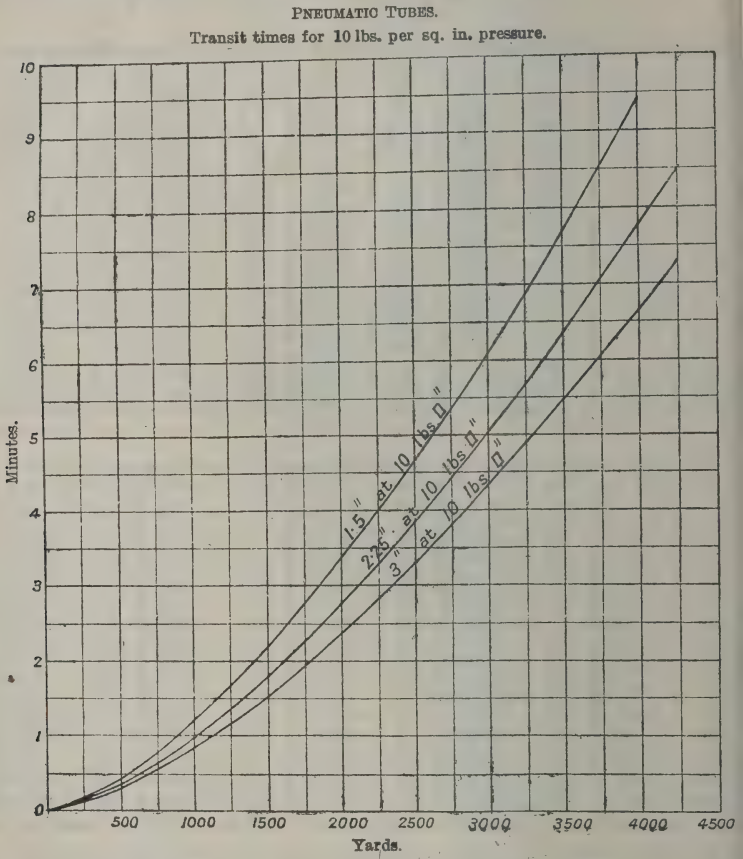

FIG. 10.

PNEUMATIC HOUSE TUBES.

These are, in the British Post Office Service, usually of brass or copper, and in some cases are operated on lines similar to the foregoing system, but considerable modifications have been introduced.

A very general system for warehouses is a circular one with loops into the various apartments which it is desired to connect.

The air is continually circulated by means of a blower of the Roots type which is joined to one end of the tube, whilst the other is open to atmosphere.

Carriers are despatched from a station by being inserted in the 'return' pipe of the loop and are received on the 'flow' pipe, suitable receiving apparatus being provided for the interception of a withdrawal of the carrier without interrupting the flow of air, which is made to travel through a by-pass.

Snifting Valves.

These valves open for the purpose of allowing the passage of air, but close if liquids attempt to pass; they are used in hydraulic systems, and also in motor-cars. In a simple form the arrangement is shown by fig. 11.

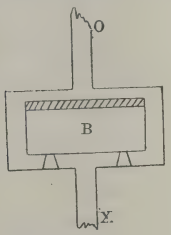

FIG. 11.

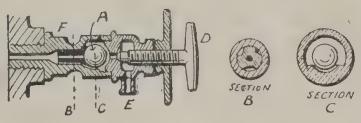

FIG. 12.

B is a light float with a leather washer at the top; O is an outlet pipe; X is the pressure system. Air is free to pass in and out, but if liquid is passing out, B is carried up and seals the outlet pipe.

In connection with air vessels for pumps, a snifting valve is utilised to recharge such with air; two cocks may be used, one at the top and one at the bottom of the vessel, so that water may be drawn off below and air re-admitted above. If it be desired to admit it automatically while at work, a 'snifting valve,' a separate air-pump, or an air-injector may be adopted. The valve, fig. 12, is placed between the suction and delivery valves, and consists of a gun-metal chamber, F, containing a ball, A, which rolls backward and forward on account of the pump stroke. When rolled leftward, air is drawn inward at E, while the escape of water on return stroke is prevented by a rightward roll, and the whole may be put out of action or adjusted by a screwed plug, D.

REFRIGERATION—REFRIGERATING MACHINERY—ICE MAKING—COLD STORAGE

(Revised and amplified by Fred. Simpson, Assoc.M.Inst.C.E.)

SECTION XXIII

REFRIGERATION—REFRIGERATING MACHINERY—ICE MAKING—COLD STORAGE.

(Revised and amplified by Fred. Simpson, Assoc.M.Inst.C.E.)

REFRIGERATION.

The mechanical production of low temperatures for commercial use is mainly based on the employment of certain substances which, as liquids, have low temperature boiling points at moderate pressures, and whose vapours are capable of condensation at a higher temperature.

The selection of such a substance is dependent on the limits of volume, pressure and temperatures available, as well as on the general properties of the substance in regard to its action on the materials employed in the construction of the machinery, its inflammability and its poisonous properties; anhydrous ammonia, carbonic dioxide, sulphur dioxide, sulphuric ether, and many other substances are available, but ammonia and carbonic acid are most generally used. In selecting between these two the fact that the critical temperature of carbonic acid occurs at about 87°F. prohibits its economical use where the temperature of condensing water available is near to or above that temperature.

The general process of refrigeration consists in exposing the surface of the vessel (the 'refrigerator') containing the working substance, to the material to be refrigerated, and maintaining in that vessel a pressure corresponding to a boiling-point temperature of the working substance somewhat lower than the degree of cooling required. This pressure is maintained by means of a gas-pump, which draws away the vapour at the rate it is formed in the process of boiling, and compresses and transfers it to another vessel (the 'condenser') in which, by means of some available cooling agent, generally water circulated round the containing vessel, it is condensed to a liquid form at the higher pressure and corresponding temperature of liquefaction. The condensing water is supplied at a temperature somewhat lower than that of liquefaction, and from the condenser in this liquid form, it is supplied as required to the refrigerator. (Fig. 1, page 1097.)

A modification of the foregoing process occurs in the 'ammonia absorption' system, the gas-pump being replaced by a vessel in which the vapour formed in the refrigerator is absorbed by cooled water at the lower pressure, and the water, when saturated with the gas, is transferred by a pump to a boiler on the higher-pressure side of the system. In this boiler the aqueous solution is heated, the disengaged gas passing off to a condenser to be cooled and liquefied, the liquid ammonia then passing as required to the refrigerator. In the larger installations on this principle, the water in the boiler, as it is deprived of the gas, is cooled and run into the absorbing vessel to replace that pumped to the boiler, and, generally, an interchange of heat from the weak liquor passing from the boiler to the saturated solution after being pumped is arranged for, but in the smaller plants the boiler and absorber are alternately substituted for each other, the action of the machine being thus intermittent. (Fig. 2, page 1098.)

In the process of raising the pressure of the vapour from that of the refrigerator to that of the condenser, the power applied reappears in the form of heat stored in the gas, and if none of this heat is allowed to escape, the temperature of the gas will be raised considerably above that at which it condenses at the higher pressure; that is to say, it will be superheated.

In practice, a large amount of this superheat escapes by conduction through the compressor walls, and in the case of what is termed 'dry compression,' is taken up by a water-jacket round the compressor. In the case of 'wet compression' the vapour from the refrigerator is delivered to the compressor supersaturated to such an extent that the greater part of the superheat is taken up in vaporising this excess of liquid.

The injection of cooled oil into the compressor during compression of the gas has also been used, with the intention of taking up part of the superheat and at the same time reducing the cylinder clearances.

The thermal changes taking place are approximately as follows:—Starting with the liquid refrigerant. At condenser pressure and temperature, this is conveyed to the refrigerator through a valve capable of sensitive adjustment; on passing this valve and arriving at the pressure of the refrigerator, the liquid is immediately reduced in temperature by the evaporation of a portion of itself; the remaining liquid, passing through the coils and distributed over their large surface, is evaporated by the heat supplied by the material to be cooled, which is correspondingly reduced in temperature. Assuming T_2 to be the absolute temperature of the condenser (that is the temperature on the Fah. scale *plus* 461°), T_1 to be the absolute temperature of the refrigerator, c to be the mean specific heat of the liquid, h_1 the heat of vaporisation at the refrigerator pressure, in British

thermal units (B.Th.U.) per lb.; then assuming that the vapour from the refrigerator arrives at the compressor in a condition of saturation, the abstraction of heat from the material cooled, for each lb. of vapour, will be

$$h_1 - (T_2 - T_1)\, c.$$

Following the course of the resultant vapour, the work of compression to the condenser pressure will be (in heat units),

$$\left(\frac{T_2}{T_1} - 1\right) h_1,$$

and the whole heat,

$$\frac{T_2}{T_1}\, h_1.$$

The amount of heat, above the refrigerating temperature, after condensation and at condenser temperature, will be,

$$(T_2 - T_1)\, c\,;$$

so that the amount of heat to be taken out in cooling during compression, and afterwards by the condensing water, will be the difference between the total heat and that remaining in the condensed liquid, or,

$$\frac{T_2}{T_1}\, h_1 - (T_2 - T_1)\, c.$$

If by means of water-jackets, or other method of cooling, the gas is cooled as it is being compressed, so that it arrives at the condenser as a vapour at condenser temperature, the heat remaining to be taken out to reduce it to liquid form would be the heat of vaporisation at that pressure (say h_2); so that the superheat amounts to

$$\frac{T_2}{T_1}\, h_1 - (T_2 - T_1)\, c - h_2.$$

This represents the amount of heat that may be abstracted during compression by the water-jacket, or supplied by the evaporation, during the compression, of the liquid carried over from the refrigerator with the vapour in what is called 'wet compression.'

In this latter case the amount of liquid required per pound of vapour entering the compressor to ensure the cooling of the gas during compression in order to arrive at the condenser at condenser temperature, would be

$$\frac{T_2}{T_1} - \frac{(T_2 - T_1)\, c + h_2}{h_1},$$

The extra liquid so entrained in the circuit reduces the refrigeration efficiency per pound of liquid evaporated in the refrigerator by the amount

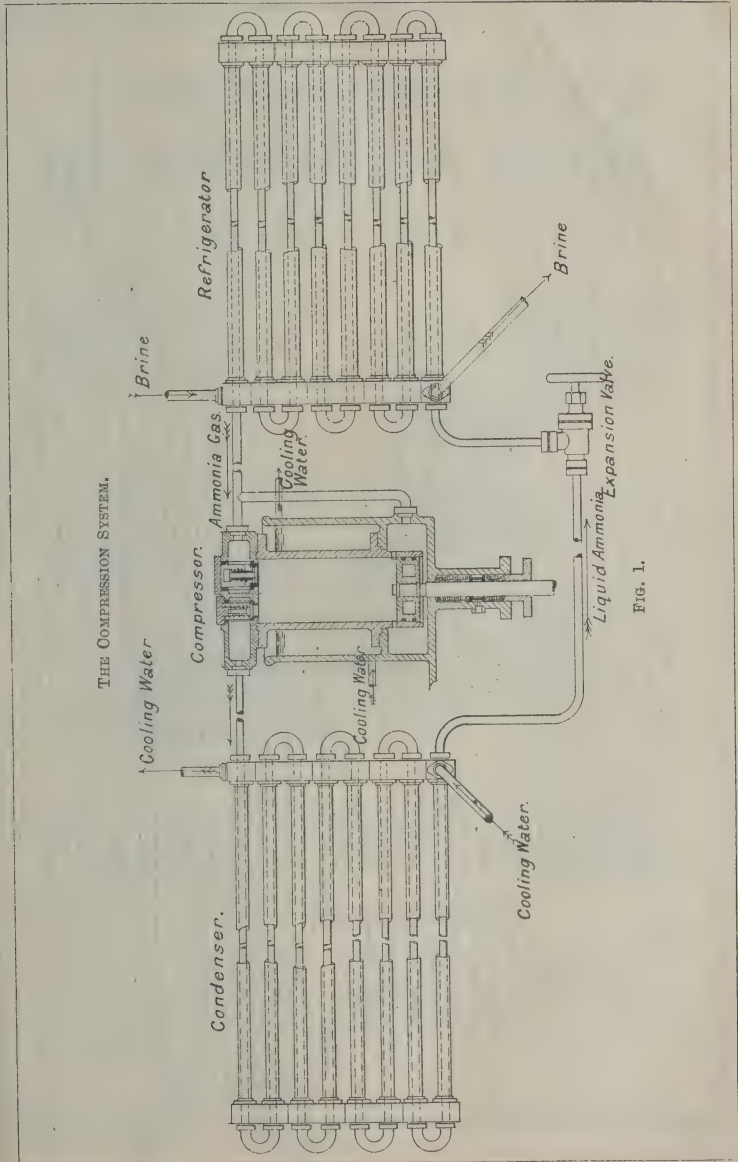
$$(T_2 - T_1)\, c \left[\frac{T_2}{T_1} - \frac{(T_2 - T_1)\, c + h_2}{h_1}\right],$$

as this extra amount of liquid has to be cooled from condenser to refrigerator temperature.

Hence, the net amount of refrigeration per pound of liquid vaporised in the refrigerator would be,

$$h_1 - (T_2 - T_1)\, c \left[\frac{T_2 + T_1}{T_1} - \frac{(T_2 - T_1)\ c + h_2}{h_1}\right],$$

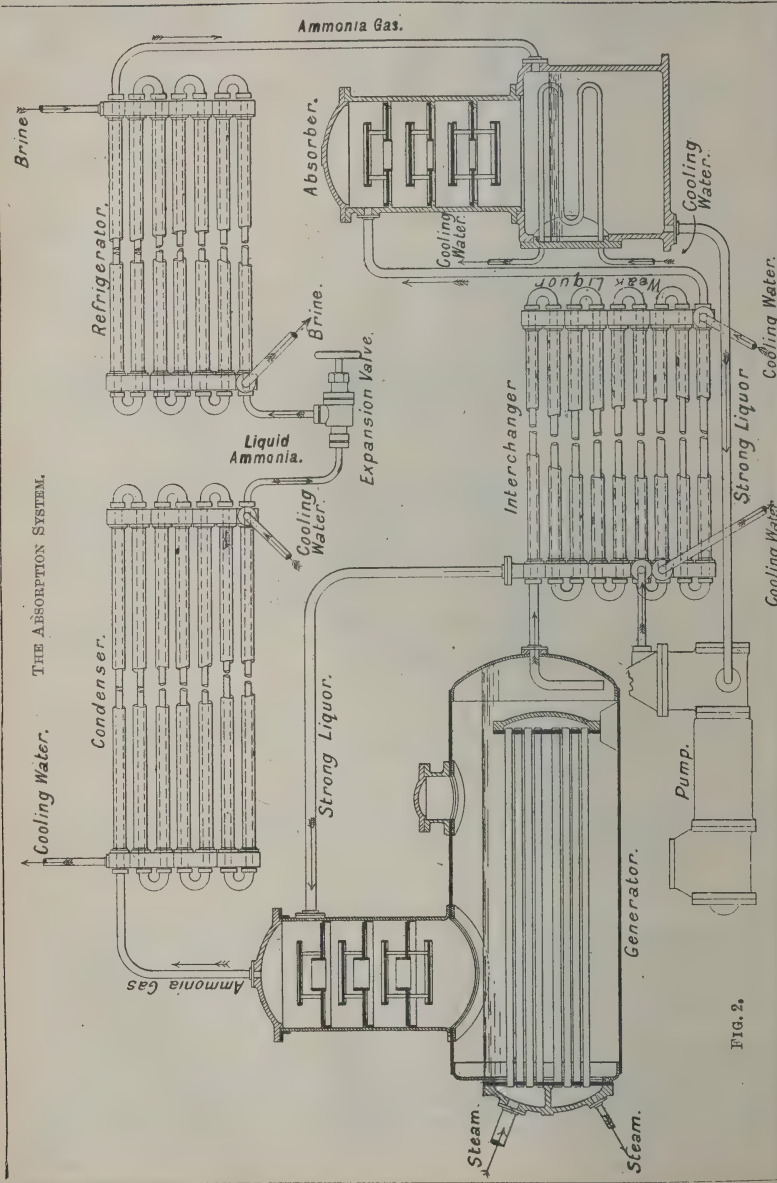
All these thermal changes are obtained by the interchange of heat, with the exception of the heat added in compression which is supplied by the conversion of the energy applied into heat, the minimum amount of work required being per pound of vapour entering the compressor.



$$h_1\, \frac{T_2 - T_1}{T_1} \times 778 \text{ foot pounds.}$$

In this formula 778 is the work in foot pounds corresponding to one unit of heat.

In place of a mean specific heat of the liquid, tables generally give the total liquid heat above and below 32° F.; the term $(T_2 - T_1)\, c$ may then be replaced by the differences of liquid heats corresponding to the absolute temperatures T_2 and T_1 on the Fahrenheit scale.



The effect of employing the 'wet compression' method, using ammonia, within moderate limits of temperature (say between 5° and 77° F.) would, if carried out with care, cause very little diminution of efficiency, but in the case of carbonic acid, between the same limits, the loss would be considerable.

In the case of ammonia, the net refrigerative effect per pound evaporated in the refrigerator between the above limits, using external cooling to take up the superheat, would be $h_1 - (T_2 - T_1)c = 519$ B.Th.U. The net effect, using entrained liquid for the same purpose, would be 510 B.Th.U. In the case of carbonic acid between the same limits, the corresponding net effects per pound of liquid evaporated in the refrigerator, using external cooling, would be 70·5 B.T.U.; with 'wet compression,' 56·5 B.Th.U. If the higher limit of temperature approaches to that of the critical temperature, the loss would be much greater.

The Refrigerator.

The Refrigerator or Evaporator usually consists of a system of tubes containing the refrigerating medium, which, in the process of boiling, abstracts heat either directly from the material to be cooled, from air which is circulated mechanically, or by invection round the tubes and then around the material operated upon; or by circulating dense brine around the refrigerator tubes and so abstracting its heat, the brine being then circulated in piping in proximity to the material to be cooled.

Each of these heat transfers requires a temperature difference depending upon the extent of the surfaces through which the transfers take place. From 3 to 5 B.Th.U. between a circulating liquid and air, and 40 B.Th.U. between a refrigerating medium and slowly moving brine, per square foot of surface per hour for each 1° F. difference of temperature, may be allowed; this latter may be increased to 150 B.Th.U. if the velocity of the brine over the surface is about 300 ft. per minute.

A much greater efficiency may be obtained by using a system of concentric tubes, one of which holds the refrigerant and the other the liquid to be cooled, the latter being circulated at a high velocity.

The Compressor.

The Compressor consists of a cylinder with a well-fitting piston which alternately draws in the gas from the refrigerator, compresses and transfers it to the condenser. The entrance and exit of the vapour is controlled by guided valves which are held to their seats by springs, and are actuated by the difference of pressure. The suction valve opens towards the cylinder, and the delivery valve towards the delivery pipe. These valves are usually situated in the cylinder covers, and care is taken in the design to reduce as much as possible the clearance passages from the valves to the interior of the cylinder; they are so constructed as to avoid damage to the rest of the machine in case of breakage. The cylinder is preferably fitted with a removable liner.

The compressor may be single or double acting, in the former case the valves are in the cylinder end cover and the stuffing-box end is exposed only to suction pressure. In the case of the double-acting compressor, the stuffing-box end is subject to the higher delivery pressure, and in that case the stuffing-box is lengthened and a lantern gland is placed between the inner and the outer rings of packing; the leakage from the compressor into this gland space is carried by a small tube to the suction side of the system, so that the outer packing has only the suction pressure to contend with.

The cylinder capacity required depends upon the refrigerant used and upon the temperature limits. For working between ordinary limits, a capacity to deal with 4 cubic ft. of gas in the case of carbonic anhydride, 20 cubic ft. in the case of anhydrous ammonia, and 65 cubic ft. in that of sulphur dioxide, is usually allowed for each 1,000 B.Th.U. of refrigeration to be dealt with.

The Condenser.

The Condenser usually consists of a nest of tubes containing the vapour from the compressors and submerged in a tank of water which is being continually renewed. In another form the condensing water is allowed to trickle over the tubes in a thin film, the whole being exposed to a current of air.

A very effective and compact form of condenser consists of a system of two concentric tubes, the vapour from the compressor passing into the space between the two; the water runs through the inner tube in a contrary direction to that of the vapour and condensed liquid, so that the heated water leaves the condenser at a point where the hot gases from the compressor enter, the work of condensation being performed with a minimum expenditure of condensing water. Experiments with this class of condenser gave a transmission per square foot per hour for 1° F. temperature difference, of about 120 B.Th.U. with a water velocity of 150 ft. per minute through the tube, to 290 B.Th.U. with a water velocity of 400 ft. per minute.

THE COLD-AIR REFRIGERATING MACHINE.

The system generally employed with this class of machine is the compression of air in a double-acting compressor with gunmetal liner forming a water jacket to about 65 lbs. on the square inch (absolute). The air is then discharged into a cooler similar in construction to a steam surface condenser, through the inside of which the water is caused to circulate. To this water the heat of compression is transferred. The air, after leaving the cooler, passes on to an expansion cylinder, where it does useful work on a piston usually attached to a continuation of the steam piston-rod. Each end of this cylinder is fitted with distinct adjustable cut-off valves.

The air, after expansion, passes through insulated ducts to the storage chamber, where it absorbs heat from the chamber and contents. It is then drawn off by suction-ducts on the opposite side of the chamber and returns to the machine, where it is re-compressed, cooled and expanded, and delivered to the room in a continuous cycle.

The foregoing may be taken as a general description of all cold-air machines, the various makers differing only in matters of detail and construction of machine.

The advantages of cold-air machines are: first, that no chemicals of any description are required, consequently their employment is not attended by constant dangers from possible

explosions and fires, or loss of life through the accidental escape of deadly gases; very low temperatures can be rapidly attained by their use; their construction is comparatively simple, and their application is easy; the entire machine is situated externally to the chamber or store being refrigerated, and every part thereof is consequently accessible at all times.

NOTES ON AIR REFRIGERATING MACHINES.

Air machines will make 3 to 4 tons of ice per ton of coal.

Air machines require 30 to 40 lbs. of water per lb. of ice.

An air machine will absorb from 600 to 700 thermal units, passing through a range of 170° F., per lb. of coal consumed.

Air machines of power to cool 100,000 cubic ft. of air per hour through a range of 160° F. can be worked with a steam engine indicating 100 to 150 h.p., with a consumption of $\frac{1}{5}$ of a ton of coal per hour.

The machine room for an 'Arctic' air machine seldom occupies more than 5 per cent. of the space being cooled. A Cole's 'Arctic' air machine discharging 100,000 cubic ft. of air per hour occupies a space of 135 sq. ft. and 776 cubic ft.; a 7,000 cubic ft. machine occupies a space of 38 sq. ft. and 280 cubic ft.

According to Coleman, air machines of less capacity than 10,000 cubic ft. of air per hour require to work at an air-pressure of not less than 65 lbs. per sq. in. for a range of cooling for 150° F. Machines dealing with 50,000 cubic ft. per hour can work at 45 lbs. pressure.

According to Haslam, to reduce air to 60° F. below zero does not require the air-pressure to exceed 45 lbs.

The ratio of the compressor and expander capacities in a cold-air machine should preferably be as 1·6 to 1.

An air machine with two compressors 16 inches diameter and 16 inches stroke, each with an expansion cylinder 12 inches diameter and 16 inches stroke, the machine being actuated by four steam cylinders 10 inches diameter and 16 inches stroke, will cool a chamber of 18,000 cubic feet capacity.

According to Lightfoot, 25 h.p. will cool 15,000 cubic feet of air per hour.

20,000 cubic feet of saturated air at 90° F. contains 42 lbs. of water.
" " " " 60° " 17 " "

To cool 1,000 gallons of water 25° F. by an air machine takes 10 tons of coal per 24 hours, or 156 h.p.

The amount of cooling water required for air-compression machines will vary with the temperature of the water-supply, and may be found approximately from the following formula:—

$$G = \frac{H}{10\,(t_1 - t_2)}$$

where,

G = quantity of water required in gallons per minute,

H = quantity of heat to be withdrawn from the air,

t_1, t_2, being the respective inlet and outlet temperature of the condensing water.

THE SULPHUROUS-ANHYDRIDE REFRIGERATING MACHINE.

The refrigerant of these machines is liquefied sulphur dioxide gas.

The gas has a specific heat of ·41 (water, 1).

It has a critical pressure of 79 atmospheres, and a critical temperature of 312° F.

The specific gravity of the gas is 2·211 (air, 1), and the specific gravity of the liquid at −4°F. is 1·49.

Machines using this agent are in a minority in this country, although used to some extent on the Continent.

They require a much greater compressor capacity than the ammonia machines—nearly three times as much—and give a low efficiency at low refrigerator temperatures.

Exceptional care has to be taken to maintain tight joints, as any leakage might produce sulphuric acid, which would become destructive to the metal of the plant.

THE CARBONIC-ACID REFRIGERATING MACHINE.

Of late years 'carbonic acid,' or 'carbonic anhydride' as it is technically known, has come very much to the front as a refrigerating agent. It has certain properties and advantages that are found suitable in some situations—mainly for marine work, in the transportation of perishable produce.

The fact that carbonic anhydride will not attack metals, and that it cannot be decomposed during compression, are the points mainly in its favour.

The gas is inodorous, and it is claimed that air containing 8 per cent. of carbonic anhydride gas can be inhaled without danger, but at higher percentages it will produce stupefaction and suffocation.

Carbonic anhydride has a specific gravity of 1·529 (air, 1), at the atmospheric pressure.

It boils at a temperature of −108° F. at atmospheric pressure.

It is liquid at 32° F. under a pressure of 36 atmospheres, and has a specific gravity of ·93 (water, 1).

The specific heat of carbonic anhydride gas at constant pressure equals ·2167 (air, ·2375).

The working pressure of carbonic-anhydride machine varies from 50 to 70 atmospheres.

Owing to the nature of the refrigerant, which evaporates under atmospheric pressure at 108° F. below zero, the diameters of all parts of the machine are very small, so that there is no difficulty in proportioning the machine to deal with its working pressure.

The efficiency of the machine is considerably lessened by the high specific heat of the liquid, and therefore decreases rapidly with a high condensing temperature.

Experiments carried out by Professor Linde some twenty years ago went to prove that these machines, when working with condensing water at 90° F., were less efficient by 50 per cent. than when the temperature of the condensing water was about 50° F.

One of the main advantages of this machine when using sea-water for condensing purposes is that the condenser coil may be made of copper, which ensures longer life, both internally and externally, as the carbonic anhydride has no chemical action on copper.

THE ANHYDROUS-AMMONIA REFRIGERATING MACHINE.

The refrigerant for these machines is liquid anhydrous ammonia.

The gas is colourless and irrespirable.

It burns with a yellowish flame if mixed with a large proportion of air.

It is exceedingly soluble in water; 1 part of water at 60° F. will absorb 800 parts of gas.

It has a very strong action on copper and its alloys.

It has a high latent heat of evaporation and a comparatively low vapour tension, admitting liquefaction at a comparatively low pressure and high temperature.

It is generally considered to be the most satisfactory and economical medium for refrigerating purposes, as evidenced by the great number of engineering firms engaged in the manufacture of ammonia machines over those using other refrigerants.

A packing for ammonia pumps, supplied by *Turner Brothers Asbestos Co. Ltd., Rochdale*, consists of yarn which is subjected to a process rendering the cotton fibres impervious to the action of the liquids. It has high-wearing qualities. A packing for ammonia pumps, in ring form, is built up from laminated layers of a specially treated fabric, and is very sensitive in its action on the rod. It fulfils the conditions of a high-class packing for the special purpose of ammonia pumps.

1 lb. liquid ammonia anhydride = ·0257 cubic ft.

The refrigeration is brought about by the evaporation of the liquid anhydrous ammonia, which takes place, generally, in coils of pipe, termed the refrigerator coils.

The ammonia vapour resulting from this evaporation, and which is at a pressure of from 10 lbs. to 30 lbs. per square inch above atmospheric pressure, is compressed mechanically up to a pressure of from 120 lbs. to 160 lbs. per square inch, depending upon the temperature of the condensing water used. Table V. gives the refrigerating effect of a cubic foot of ammonia gas at different condenser and back pressures.

During compression, heat is developed in proportion to the relative volume to which the gas has been reduced. This high-pressure gas is now discharged into the condenser—usually the double tube or the open-air evaporative type when used for land service—where the heat of compression is absorbed by the condensing water. When this stage in the cycle is reached, the gas assumes the liquid condition, and is then led by suitable pipes and connections to the expansion or refrigerator coils, where it re-evaporates on passing an expansion valve that separates the high-pressure liquid from the low-pressure gas, absorbing, from the coils and substances in proximity thereto, a quantity of heat proportionate to that which was previously given up by the high-pressure gas to the water of condensation.

Modifications of the foregoing, and other auxiliary processes, have been introduced by several makers of ammonia machines; but the general principles remain the same, the operations of the refrigerant forming a complete cycle.

In the working of a plant care should be taken that the liquid ammonia is kept at a temperature as low as, or lower, than the temperature of the condensing water, in its passage from the condenser to the expansion cock, as any heat taken up, tending to raise the temperature of the liquid, detracts from the efficiency, besides causing trouble through the generation of vapour and consequent tendency to block the system.

To successfully operate a refrigerating plant the care of the various temperatures is of importance. Thermometer wells should be freely distributed at the various points, viz. :—

(1) In the ammonia suction immediately entering the compressor.
(2) In the ammonia discharge immediately leaving the compressor.
(3) In the ammonia discharge immediately entering the condenser.
(4) In the liquid discharge immediately leaving the condenser.
(5) In the liquid manifold immediately at the refrigerator.
(6) In the suction manifold immediately leaving the refrigerator.
(7) In the brine supply immediately entering the refrigerator.
(8) In the brine return immediately leaving the refrigerator.

Indicator Diagrams of Compressors.

Indicator diagrams may be utilised not only for estimating the work done in the compressors, but also for discovering defects or irregularities in the action of the compressors.

In order to understand the meaning of any irregularity in the diagram, assume first that no

mechanical defects are present, and that the pressure curve is only influenced by heat exchanges; then the line of pressures will be between the limits of the curve of pressures representing the compression of a perfect gas, without loss or gain from outside heat influences, and that of a vapour kept in a state of saturation by the abstraction of superheat as it is formed in the process of compression. To follow the first line, a perfect heat insulation would be required, and to follow the second the compressor walls must have a temperature lower than that of the gas at the various stages of compression, in order to take up the superheat; so that in the first stages of compression the temperature of the compressor must be that of the suction gas, a condition only to be obtained at the expense of the general efficiency of the system.

An approach to a practically perfect condition of working in a water-jacketed compressor would be represented by a curve following the adiabatic curve until the temperature of the gas reaches that of the cooling water in the jacket. The jacket then coming into action, the heat formed by the further compression is taken up by the cooling water, and the temperature of the gas kept down, so that the gas arrives at the condenser pressure at the temperature of the condenser and in a saturated condition. This presupposes a perfect conduction to the water jacket and that the action of the jacket is only effective in taking up heat; but as it would be equally effective in giving out heat, when the gas was at a lower temperature, there would be an initial heating of the gas to some extent.

The water jacket not being perfect in action we have in practice some intermediate effect which tends to raise the pressure line at the start of compression, and lower it towards the end, so that the volume at the termination lies between that corresponding to the adiabatic compression and that corresponding to the saturation curve. As the effect of superheating from the jacket has its greatest value during the filling of the compressor with the suction gas, its effect would be comparatively slight (during the period of compression) until the gas heated by compression arrived at the temperature of the jacket, when the heat transfer would be reversed, and a cooling of the gas effected up to the end of the stroke.

With the exception of a slight absorption of heat, which might tend to raise the pressure above the adiabatic curve at the start of the stroke, the diagram curve must occupy a position between the lines representing the adiabatic curve of pressures and the saturation curve, that is if the compressor is fed with saturated vapour or superheated gas and the mechanical adjustments are perfect.

To appreciate the action going on inside the compressor, these two curves, corresponding to the adiabatic compression and to the compression of a saturated vapour, should be drawn on the diagrams or on tracing paper and superposed.

To construct these curves, assume V_o = the volume of the compressor, and P_o = the suction pressure above vacuum. Then for any other volume, V_x, the corresponding pressure P_x would be $\frac{V_o^n}{V_x^n} P_o$. If V_o is taken as a unit volume, then $P_x = \frac{P}{V_x^n}$. The index n varies with each gas, and in the case of nearly perfect gases compressed or expanded adiabatically, it is the quotient found by dividing the number representing the specific heat of the gas at constant pressure by that of the specific heat at constant volume. But n in the case of *im*perfect gases may be approximated to empirically, thus $n = 1{\cdot}30$ in the case of ammonia anhydride compressed adiabatically, and $n = 1{\cdot}06$ for the same gas compressed and maintained in a just saturated condition during the process of compression.

In the formula given, if V_x is taken successively as $1, {\cdot}9, {\cdot}8, \ldots\ldots {\cdot}2, {\cdot}1$, a series of factors $\left(\frac{1}{V_x^n}\right)$ may be obtained, which multiplied into the value of P_o (the initial pressure) will give the pressure corresponding to the respective volumes.

Table No. VIA gives the value of these factors for $n = 1{\cdot}06$, $1{\cdot}10$, $1{\cdot}16$ and $1{\cdot}30$. The factors in the column under $n = 1{\cdot}06$ and $1{\cdot}30$, represent respectively the saturation and adiabatic curves for anhydrous ammonia; factors under $n = 1{\cdot}10$ represent the approximate curve which ought to be obtained with liquid ammonia injection, and factors under $n = 1{\cdot}16$ give approximately the curve claimed by the advocates of the 'wet' system of compression.

TABLE VIA.

·2	5·51	5·76	6·47	8·10
·1	11·48	12·59	14·45	19·95

In practice the construction of these curves will be facilitated by the use of the slide-rule; if a strip of paper is marked with the values of the factors taken from the scale of the slide-rule and numbered 1·0, ·9, ·8, etc., then if 1·0 on the marked scale is placed to the number on the slide-rule corresponding to the initial (suction) pressure, the pressures corresponding to the other ordinates will be found on the slide-rule scale opposite to the respective number on the paper slip.

A line is drawn, on the indicator diagram, parallel to the atmospheric line and 14·7 lbs. on the scale of pressures, below it, representing the line of absolute zero pressure or vacuum; the diagram is divided into ten equal spaces by lines at right angles to the atmospheric line, the line through the toe of the diagram being numbered 1·0 and the others ·9, ·8, ·7, etc., successively; the calculated ordinates corresponding to the adiabatic and saturation curves are then plotted on the corresponding lines, from the vacuum line as a base, and the respective curves drawn through the points so determined.

Fig. 3 shows such a diagram with the adiabatic and saturation compression curves superposed; the suction pressure in this case being 30 lbs. (absolute) per square inch, and the condenser pressure 150 lbs. (absolute).

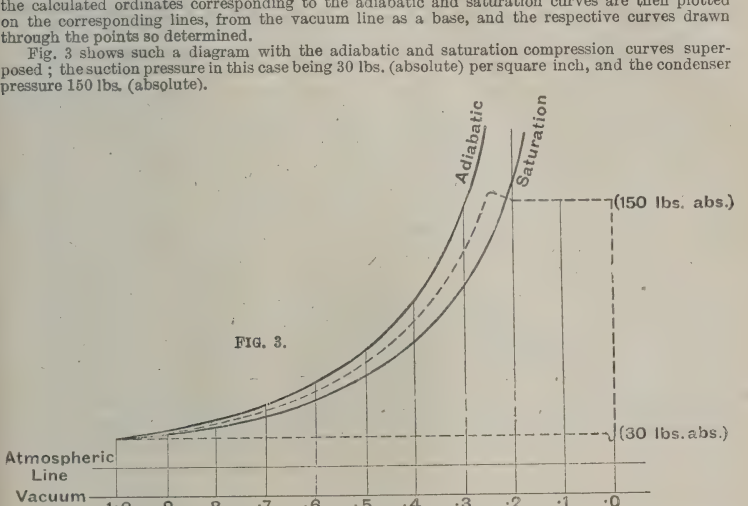

FIG. 3.

The actual indicator diagram will, in ordinary cases, lie within the area between the adiabatic and saturat on curves plotted on the diagram (fig. 3) by the above method.

In considering the influence of mechanical defects upon the shape of the diagram, only those affecting the volume and pressure would be noticeable. These may be due to leakages past suction and delivery valves, or past the piston, and from the effect of excessive clearances. Taking the effects of these in order, any leakage past the suction valve during compression would allow of an escape of gas into the suction pipe and so diminish the pressure in the compressor, which would be indicated by the compression curve tending to approach or pass under the saturation curve; any leakage in the delivery valve would tend to make the compression curve approach the adiabatic curve; and any leakage past the piston would cause the compression curve to approach or pass the saturation curve.

In the diagram of the suction stroke with perfect mechanical conditions, the pressure line ought to drop immediately to slightly under suction pressure, but with a small clearance the pressure will not be lowered sufficiently for the suction valve to open, until the gas in this clearance space has re-expanded. Any leak from the delivery pipe, or any deposit of liquid ammonia on the piston or cylinder ends, which may take place in 'wet' compression, may cause a delay in the lowering of the pressure to that of the suction.

Once the suction valve opens, allowing the passage of the suction gas to the compressor, the pressure line will not materially vary, and will continue as a line parallel to the vacuum line to the end of the suction stroke, the cylinder being then full of gas at practically suction pressure.

At the end of the compression curve a slight rise in the pressure above that of the condenser may be registered on the diagram, due to excessive strength of the springs on the delivery valves; a similar defect in the suction valves will be indicated by a depression of the suction line, showing a pressure below that of the refrigerator, at the opening of the suction valves.

Calcium Brine.

Calcium Chloride Brine of a density ranging from 1·18 to 1·25 is usually employed. In estimating the weight of calcium chloride required to produce brine of a given density regard must be

had to the fact that the commercial calcium chloride contains a large amount of water of crystallisation. An approximate rule is to multiply the density by 20 and subtract 20·1, the remainder gives the number of pounds of commercial calcium chloride required for each gallon of brine of the required density; for example, take the required density at 1·20, then $1{\cdot}20\times20-20{\cdot}1=24-20{\cdot}1=3{\cdot}9$ lbs. per gallon of brine.

ICE MAKING.

One of the principal uses of mechanical refrigeration is in the manufacture of artificial ice, and the methods most generally used are the 'can,' 'cell,' and 'plate' systems. The foregoing are in order of cost of production and also in quality of ice made.

'Can' ice is produced simply by suspending a can of fresh water in brine at a temperature of from 10° to 15° F.

'Cell' ice is produced by circulating cold brine through the hollow walls of the cells, the cells being filled with fresh water.

'Plate' ice is produced by freezing from one side of a hollow plate only, cold brine or ammonia (or other refrigerant) being circulated through the hollow plate.

'Can' ice is the cheapest to produce and the poorest in quality. With brine at a temperature of 14° to 15° F., 11 ins. ice will take about 45 to 50 hours to freeze, and 10 ins. ice about 38 to 44 hours. The time to freeze different thicknesses of 'can' ice is approximately about equal to the square of the thickness divided by 2.

Table VII., p. 1106, compiled by Skinkle, gives particulars of some ice-making tanks, piping, moulds, etc., in actual operation.

One cubic foot of ice weighs 57½ lbs. at 32° F.

Ice expands 8½ per cent. by freezing.

One ton of refrigeration equals 318,080 B.Th.U.'s—that is, the amount of heat that would be necessary to convert a ton of ice at 32° F. into a ton of water at 32° F.

An average expenditure of from 50 kilowatt-hours to 60 kilowatt-hours is said to be required to produce one ton of ice by means of a motor-driven ammonia-compression system. The maximum demand of such an outfit reaches about 2·3 kilowatts per ton of ice-making capacity. Of this demand about 1·5 kilowatt per ton is due to the compressor itself, the remainder representing the work of the auxiliary apparatus. These figures represent the conclusions reached by a large central station company after a study of a number of ice-making plants where electrical energy is used in motor-driven compressors.

Water Coolers.

THE 'HEENAN' WATER COOLER.

The latest type of cooler recently introduced by Messrs. Heenan & Froude, Ltd., Worcester, claims a minimum consumption of water per brake horse-power-hour, and has the advantage of being compact and occupying comparatively small space. The apparatus is also self-contained. It is of the stationary type, and has no moving parts beyond the fan which circulates the air, and the pump which circulates the water.

The apparatus (as shown by fig. 4) consists of an outer casing, which is rectangular in shape, built up of mild steel plates. The base of this casing forms a tank into which the water drains after cooling, and previous to re-circulation.

The cooling effect is obtained by evenly distributing the heated water over a number of screens set up one above the other in the body of the cooler.

The water to be cooled, after passing through a strainer, enters at the top of the cooler and falls on to the screens through nozzles which feed perforated troughs. In its fall through the screens it meets a current of cold air which is forced upward through the casing by a centrifugal fan, the discharge from which is introduced to the underside of the lowest screen.

The screens are formed of phosphor-bronze metallic wool of standard size and thickness, held together between brass wire netting which is attached to galvanised angle-steel frames.

The cooling effect is positive and continuous, the cooling surface being always efficient, and the volume of air being a predetermined quantity which is not dependent on climatic conditions. By suitably proportioning the size of the machine for the duty which it has to undertake, water can be cooled down to a temperature closely approaching that of the prevailing wet bulb thermometer. Thus in hot weather—in temperate as well as in tropical climates—re-cooled water can be provided at a temperature considerably below the dry bulb temperature of the surrounding atmosphere. This feature renders the machine especially suitable for dealing with the circulating water of refrigerating plants, for which purpose large numbers of 'Heenan' coolers have been supplied. The practical value of the cooler is due not only to the saving in water but to the improved efficiency of the refrigerating plant, resulting in lower compression pressures and reduced power consumption.

'HEENAN' COOLER. TYPE 'V.'

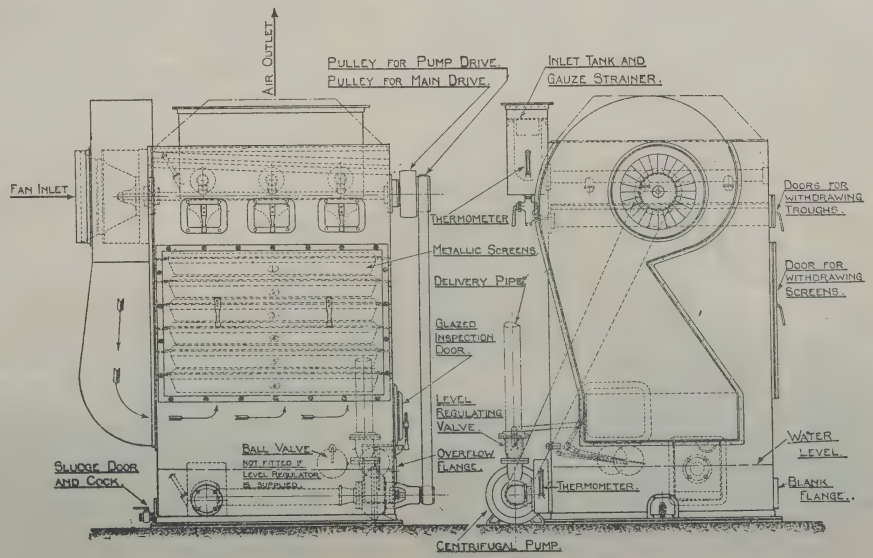

FIG. 4.

COLD STORAGE.

Temperatures below zero Fahrenheit are hardly of any utility in cold storage, although in some instances even lower temperatures are produced. A room piped about 4 cubic feet of space to 1 lineal foot 1-inch pipe direct ammonia expansion could be brought to 8° F. below zero. Theoretically a temperature of —28° F. can be produced with ammonia refrigeration at a back pressure equal to that of the atmosphere (and even lower at lower pressures), but practically it is not likely that temperatures lower than —20° F. can be obtained with ammonia, although it may be done by carbonic acid.

A small rotary fan, located in the engine room and connected with the storage rooms by galvanised iron pipes provided with gates or valves, is a very efficient device to remove foul air.

Allow 3,000 to 5,000 cubic feet space per ton of refrigeration in 24 hours in chilling rooms, and 5,000 to 8,000 cubic feet space per ton of refrigeration in 24 hours in storage rooms, according to insulation, size of rooms, and other conditions.

INSULATION.

In addition to the work of refrigeration proper a large proportion of additional work is required in taking up the leakage of heat through the walls of the refrigerating chambers, and it is necessary that these walls should be constructed with materials that will reduce this leakage to a minimum.

The materials most generally used for the purposes of insulation and which give satisfactory results are charcoal, mineral or slag wool, and cork—either granulated or compressed into blocks; these materials should be protected from moisture by a perfectly watertight and dampproof covering. Besides their non-conducting properties the materials used in insulation should possess no attraction for moisture, be uninflammable, no tendency to spontaneous combustion or smouldering, should be inodorous, possess high specific heat, and pack well in place with no tendency to settle.

The usual form of building consists of outside walls of brickwork, preferably waterproofed on the inner surface with a coating of pitch; on the inside, vertical battens are secured to the walls on which a double boarding ½ in. or 1 in. thick with a sheeting of one or two thicknesses of waterproof paper between; inside this sheeting studs are spaced at convenient intervals, having a depth of the proposed thickness of the (particular) insulating material; to the inner sides of these studs is secured a double boarding with waterproof paper between, the space between the double sheeting being well filled with the selected insulating material.

The floors, ceilings and partitions are similarly constructed, the insulating material being packed between the joists, double sheeting, between the boards of which waterproof paper is placed. The boards forming the floors are of increased thickness to correspond to the weights it has to carry.

Slag Wool Insulation.

Slag wool or silicate cotton is now being largely adopted in the place of charcoal and other materials, for the purpose of insulation, in floors, walls, and ceilings of cold storage chambers.

The application of slag wool varies with the different plans of construction and the exposure of the walls to be insulated, and in modern practice a thickness of 11 ins. in the floors and 9 ins. in the walls is frequently adopted, the fact being recognised that, although perhaps a lesser thickness would suffice, the extra first cost of the greater thickness is amply repaid by the resulting economy in working.

In a frame building where slag wool is the only protection, a minimum thickness of 11 ins. is recommended.

In all cases the insulating material should be kept dry by bituminous felt or waterproof paper applied on both sides of the material, preferably between double match-boarding, dryness being an essential point in non-conducting materials.

The slag wool should not be jammed into place to break the fibres, but should be packed lightly although compactly, care being taken to fill all the space completely.

In converting slag into slag wool, it has been found that the material increases in bulk twelve times, so that the resulting fibres encase eleven times their bulk of air. In other words, a given volume containing 100 per cent. of material before conversion into the wool contains afterwards but 8 per cent., the remaining 92 per cent. of the volume being air held in close confinement in the innumerable air cells.

The weight of slag wool of the best quality is about 10 lbs. per cubic foot, costing about 5*d.* per cubic foot.

Slag wool besides being one of the best non-conductors of heat has also the advantages of being absolutely fireproof, rot-proof, and vermin-proof.

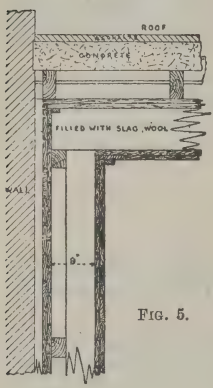

FIG. 5.

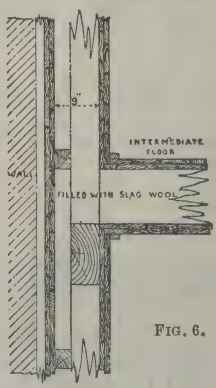

FIG. 6.

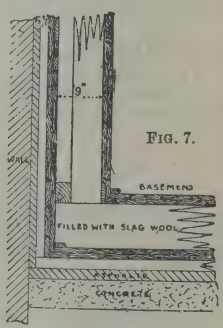

FIG. 7.

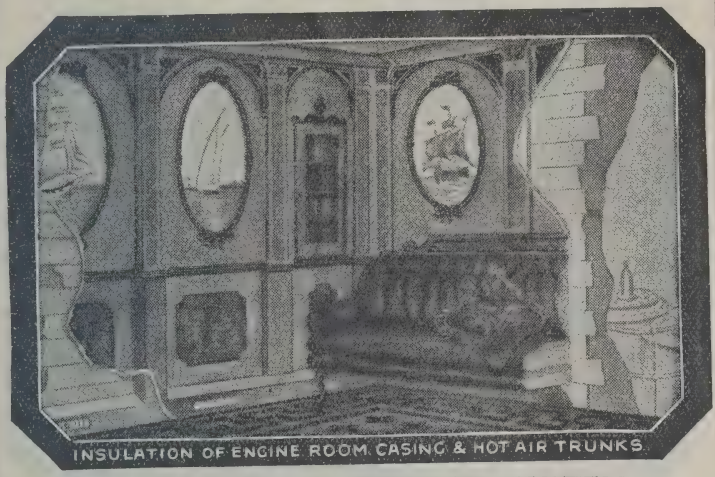
For large refrigerating stores for meat and other purposes the method adopted by Mr. Herbert Birkett, M.I.Mech.E., which is shown by figs. 5, 6, and 7, is one of the best that can be employed, waterproof insulating paper being placed between the matchboarding.

Paper Insulation.

A special description of paper known as 'Willesden' paper (*The Willesden Paper and Canvas Works, Ltd.*) has for many years been largely used in the insulation of cold storage chambers. The usual method of constructing these chambers is to erect vertical studding at certain distances apart, and to cover this on both sides with grooved and tongued matched boarding, then to cover that in its turn with the Willesden paper, and over the paper to again fix another surface of matched boarding. There is then left a space between the two erections of matched boarding and paper equal to the width of the studding used, and this space is filled with some insulating material, such as charcoal, slag wool or rice husks, etc., and the work is done. The main use of the paper is to exclude air, and the Willesden material is preferred because of its durability and strength, and because it is not affected by damp nor liable to harbour fungoid growth.

'Neponset,' 'Ko-sat,' and 'Coted' are special papers of the highest grade, which are impervious to air and moisture under the severest conditions, and are largely used for cold storage insulation. They are made in rolls 36 ins. wide containing 1,000 sq. ft.

Cork Insulation.



The application of compressed cork slabs for insulation purposes is becoming more general, both in the U.S. and in England. Being in the form of slabs which are manufactured in various shapes and dimensions, they are easily fitted to the walls of the chamber. By being built together in various layers, breaking joint and cemented with a waterproof cement, they form an impermeable insulating lining to the chamber.

The interior facing to the chamber is usually of a special cement, preferably without joint.

With this system of insulation (fig. 8) a less thickness is required as compared with the insulating materials of a loose granular nature, and it has the further advantage of giving an increased capacity to the chamber. *Messrs. Thomas Anderson Ltd., Liverpool*, have had considerable success in its application. The efficacy of their preparation is illustrated by a

recent case in which the insulation of a steamship, which had been submerged for weeks, on being raised was found intact, not requiring renewal or repair.

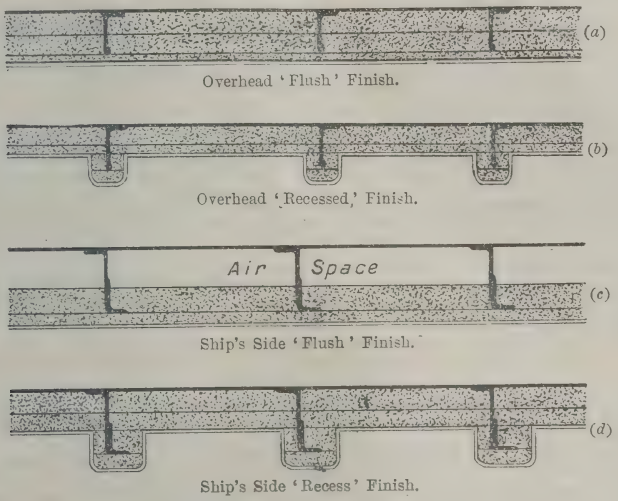

FIG. 8.—Palladeum Jointless Insulation on Cork Slabs.

Heat Transmission through Insulation.

In a building where the framework and supporting columns are of steel these should be insulated in such a manner as to prevent the conduction of heat from the outside to the interior of the building.

The outside heat is communicated to the outer surface by radiation from surrounding buildings, etc., and by contact with the air; the heat thus communicated to the surface is transmitted to the interior by conduction through the walls and insulating material; the rate will vary in proportion to the temperature difference between inside and out, also to the amount of surface exposed and to the conductivities of the materials employed.

Radiation per square foot 1° difference may be taken, assuming brick or plaster surfaces as 20 B.Th.U. per 24 hours. Loss by contact with air, per square foot 1° difference may be taken as 10 B.Th.U. per 24 hours. The combined effect of radiation and air contact, 30 B.Th.U. (reciprocal ·033). The following gives the conductivity of a few materials very generally used, per sq. foot 1 in. thick, for a temperature difference of 1°F. per 24 hours.

	B.Th.U.	(reciprocal)
Concrete	106	(·0094)
Brick	110	(·0091)
Timber from	23	(·043)
Timber to	18	(·056)
Charcoal	16	(·0625)
Charcoal (flaked)	15	(·067)
Silicate Cotton	14	(·071)
Cork	10	(·100)

To find the combined conductivity per 1° difference between the inner and outer temperatures per square foot of surface for 24 hours :—

Add the respective reciprocals of the conductivities multiplied by the thickness in inches of each of the component parts, together with the reciprocal of the effect of radiation and air contact

(·033) for each surface exposed to air and radiation; then the reciprocal of this sum will be the combined conductivity.

Taking as an example a building with 9-in. brick walls, two 1-in. boards, 9 ins. of charcoal and an inner lining of two 1-in. boards.

The combined conductivity would be

$$\frac{1}{\cdot033+(\cdot0091\times9)+(\cdot043\times2)+(\cdot0625\times9)+(\cdot043\times2)+\cdot033}=\frac{1}{\cdot8824}=1\cdot133\text{ B.Th.U.}$$

per 24 hours for each square foot of surface per degree difference of inner and outer temperatures. So that for a difference of 72° (say from 77° F. to 5° F.) the transmission of heat would be $72\times1\cdot133=81\cdot6$ B.Th.U. per square foot in 24 hours.

Multiplying this 81·6 successively by each factor of the numerator will give the respective drop in temperature in passing through each successive layer; so that $81\cdot6\times\cdot033=2\cdot7$ will be the drop in temperature of the surface of the brickwork, the surface temperature being $77-2\cdot7=74\cdot3°$; then passing through the brickwork the drop would be $\cdot0819\times81\cdot6-6\cdot6°$, so that the inner surface of the brickwork would be $74\cdot3-6\cdot6=67\cdot7°$, which would also be the temperature of the outer skin of the first boarding. Proceeding with each layer in the same manner we find 7·7° as the inside temperature of the insulation, that is, $\cdot033\times81\cdot6=2\cdot7°$ above the temperature of the air inside the chamber (5°), the temperature differences thus found between the inner and outer surfaces of each layer being those necessary in order to transmit 81·6 B.Th.U. through that layer in 24 hours.

The results thus obtained must be taken as representing the maximum of insulation. The actual results in practice will be modified by the care taken in construction, especially as to the keeping out of moisture and the selection and packing of the material. Dampness may more than double the conductivity of most of the porous materials.

Piping of Rooms.

For chilling rooms, 1 running foot of 2-inch pipe (or its equivalent) is allowed for 13 to 14 cubic feet of space in case of direct expansion, and for 7 to 8 cubic feet of space for brine circulation.

For storage rooms, 1 running foot of 2-inch pipe is allowed for 45 to 50 cubic feet in case of direct expansion, and for 15 to 18 cubic feet in case of brine circulation.

For freezing rooms, 1 running foot of 2-inch pipe is allowed for 6 to 10 cubic feet of space for direct expansion, and for 3 cubic feet of space in case of brine circulation.

Others proportion the piping by the number of animals slaughtered, allowing 13 ft. of 2-inch pipe per ox, and 6 ft. of 2-inch pipe per hog, in case of direct expansion in chilling-room. In case of brine circulation, 13 ft. of 1¼-inch pipe are allowed per hog, and 27 ft. of 1¼-inch pipe per ox. (*Siebel.*)

The moisture depositing pipes for a 20,000 cubic feet chamber occupy about 300 cubic feet, or 1½ per cent. to 2 per cent. of total space room.

About 600 square feet of pipe-surface in the case of chambers cooled by pipes will lower 20,000 cubic feet of air per hour 20° F.

SHIP REFRIGERATION.

The refinements exacted in the present-day carriage of chilled meat have led to a great improvement in the methods of control in the ship's chambers. One of the latest innovations has been the adoption of the closed system in which no open brine tanks are employed (fig. 9).

In this system the brine is pumped from the brine cooler, or evaporator, through a main to one or more distributing headers, provided with valves from which the brine leads are carried to the various sections of the chambers in the holds or 'tween decks. Corresponding collecting headers receive the return leads of the various sections; these collecting headers are in turn connected to a return brine main leading back to the evaporator.

In this system no open brine tanks are necessary and the aeration of the brine and the possibility of overflow or drawing-in of air are avoided.

In adopting this system it is necessary to employ some arrangement by which the rate of circulation is indicated; for this purpose Simpson's flowmeter, fig. 10, has been used with satisfactory results. This instrument consists of a pipe section which forms part of the circuit; this section contains a taper-shaped piece which causes a slight difference of pressure varying with the velocity of flow; this difference of pressure is measured by a very sensitive gauge which indicates the flow in gallons per hour or any other convenient unit. In order to avoid a multiplicity of gauges on a large system, the leads may be grouped into sections; the gauge pressure-tubes of the latter are connected to two headers, and provided with cocks so that any corresponding two pressure-tubes can be connected to the respective headers. These headers being connected to the gauge, the pipe sections have means for fine adjustment so that the gauges and pipe

sections are respectively interchangeable. A supplementary instrument is incorporated in each gauge for testing for leakage in the circuits.

In vessels engaged in the carriage of chilled beef and frozen meat it is necessary to adjust the temperature of the chambers apportioned to each class, both in respect to the leakage of heat from the atmosphere or sea as well as that from or to chambers adjoining which are being maintained at different temperatures. To effect this adjustment and in order to have a full flow of brine with a consequent small difference of temperature between ingoing and outcoming brine, which is necessary in the case of chilled meat, where the chamber temperatures must be kept within

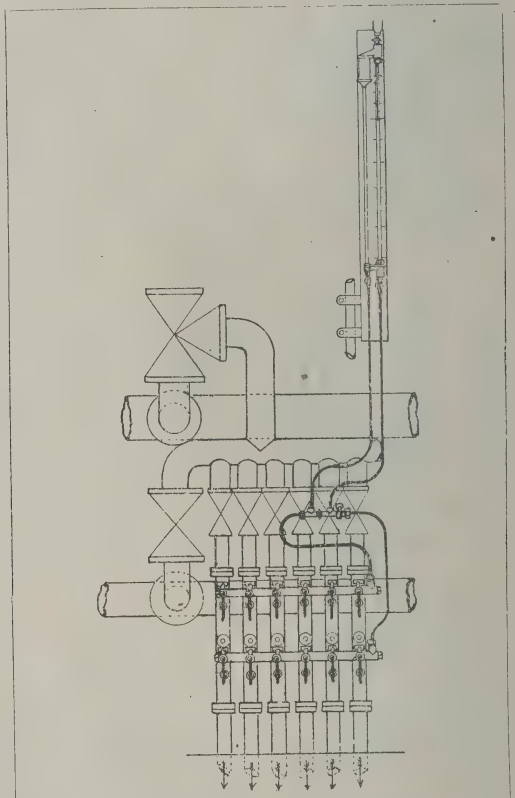

FIG. 10.—'Flowmeter' Arrangement.

narrow limits, it is convenient to have brine at two temperatures, one at the highest temperature required and cold brine as low as the coldest circulation required. These are mixed or attemperated to give any desired temperature brine between the above limits. In addition to this a thawing-off arrangement is adopted in which the brine can be heated by steam coils and circulated through any desired part of the system for the rapid thawing-off of the chambers when emptied.

The diagram fig. 10 represents such a perfected arrangement adopted by the Liverpool Refrigeration Co. Ltd. In this it will be seen that two independent pumps are provided and two systems of mains with cross-connection at each distributing header governed by an attemperating valve,

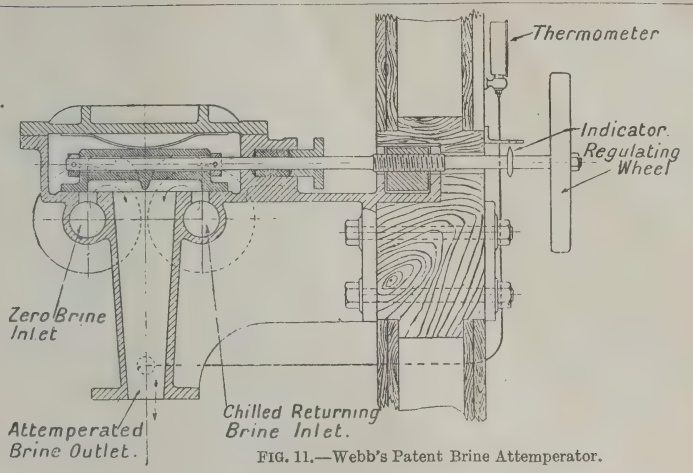

FIG. 11.—Webb's Patent Brine Attemperator.

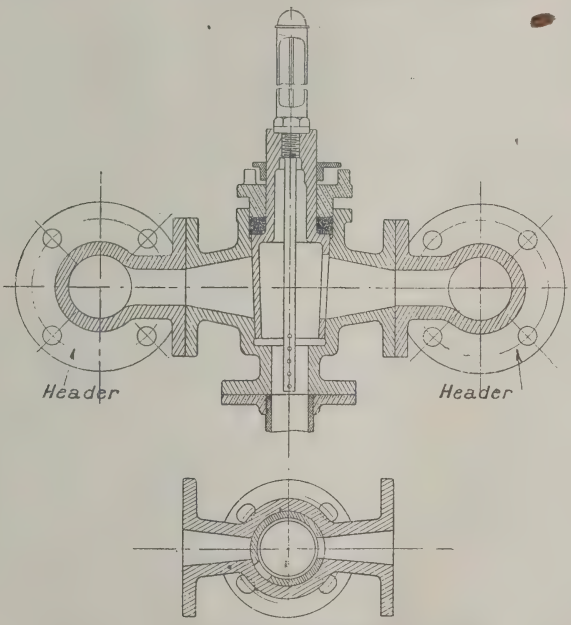

FIG. 12.—Webb's Patent Attemperator Cock (Section).

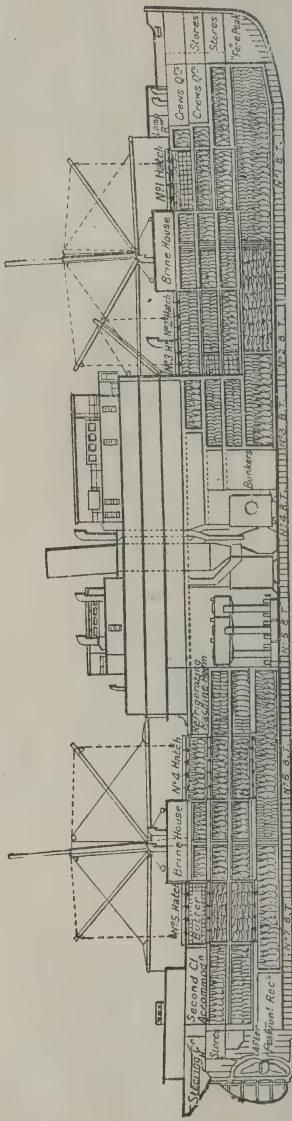

FIG. 13.—Longitudinal Section of a Modern Meat-carrying Steamer.

so that any desired proportion of cold and warm brine may be mixed to produce the desired temperature for circulation in the chambers. The return brine is collected and drawn on by the attemperated brine pump for recirculation, being mixed with cold brine at the main attemperation.

The cold brine returns are led directly to the evaporator as well as the overplus of the attemperated brine return.

Figs. 11 and 12 show the form of main attemperating valve and attemperating cock of the Liverpool Refrigeration Co., Ltd.; these as will be seen, adjust the proportion of chilled or cold brine in such a manner that the one supply is out off in proportion to the amount the other is opened up.

In the 'Octopus' Combined Feed and Return Brine Distributor and Collector (the invention of Mr. Taylor, of the Swift Beef Co.) three temperatures of brines are dealt with, giving a much larger range of control, brine being capable of distribution at a frozen, chilled, or warm temperature, or in any proportion of chilled and frozen mixed, or chilled and warm mixed, through one side of the cock and into a pipe leading from the bottom of the cock to any section or sections of brine piping; the returns from these sections being led into the bottom of the cock on the other side and, from there, diverted into the warm, chilled, or frozen returns or any combination of these in the same proportion respectively as they were delivered, so that by a single movement the distribution is proportioned and the returns are divided automatically.

The thawing-off system consists of a brine heater, an independent circulating pump, and independent mains which can be connected through cocks to each distributing and collecting header. When thawing-off, the cold and attemperated brines are both shut off from any headers corresponding to the chamber to be thawed off; the warm thawing-off brine can then be circulated in that section without interfering with the freezing or work in other chambers.

REFRIGERATING MACHINERY FOR SHIPS.

In large plants the machines should be either in duplicate or triplicate. In figs. 13 and 14 is illustrated a general arrangement of a refrigerating plant (designed by A. R. T. Woods, M.I.N.A.) dealing with 350,000 cubic feet of insulated space. The ammonia compressors and engines are triplex. The driving engine is triple expansion with three-throw crank and heavy fly-wheels, but each cylinder can be run as a high-pressure engine or the h.p and i.p. cylinders or the i.p. and l.p. cylinders can be run in combination as a compound engine. The compressors are driven off the steam cylinder tail rods, and any combination of the compressors can be worked by any of the above combinations of the steam cylinders.

The ammonia condensers are arranged in vertical sheets of piping, horizontal plates guiding the condensing water in such a manner that the cold water flows in the opposite sense to the condensing ammonia vapour: each sheet may be removed and replaced without interfering with any other sheet. The three evaporators are similar to and interchangeable with the condensers.

The brine pumps are grouped so as to be interchangeable and used in any combination either in chilling or cold brine services or on both. Another pump is provided for supplying make-up brine, for thawing off or for brine circulation in conjunction with the other pumps.

Insulation.

Over tank tops grounds 3 ins. by 3 ins. are laid athwart ships at about 18-in. centres apart, forming a three-inch air-space. These grounds support P. T. & G. boards, 1¼ in. thick laid fore and aft, and on which is placed a sheeting of tarred felt; over this a second layer of P. T. & G. boards ¾ in. thick is laid. Grounds 6 ins. by 3 ins. are then placed over the 3 ins. by 3 ins. grounds, the spaces, 6 ins. in height, between these grounds being filled with insulating material, preferably granulated cork; a decking of two layers of 1½ in. P. T. & G. boards, with tarred felt between, is laid over this.

On the ship's sides grounds are arranged, by two strips about 3 ins. by 2 ins. placed one on either side of frame and wedged in position, forming a 3-in. air-space. One-inch P. T. & G. boards are fitted, fore and aft, between the frames and nailed to the grounds; over this boarding two layers of heavy waterproof paper are tacked. Vertical grounds are then bolted to the inner sides of frames, and on to these grounds are nailed 1½-in. and ¾-in. P. T. & G. boards with two layers of heavy waterproof paper between. The space between the front and back boarding, 6 ins. to 8 ins., is filled in with insulating material, preferably granulated cork, silicate cotton, or charcoal.

In some cases the air space next to the skin of the vessel is omitted, the insulating material being filled in between the ship's plating and the inner wooden sheeting; generally a thickness of from 8½ ins. to 11 ins. of insulating material is provided for.

The insulation of the ceilings under decks is supported by grounds bolted to the beams, with a double boarding of 1 in. and ¾ in. P. T. & G. with two layers of heavy waterproof paper between. The space between the deck plating and this boarding, usually about 12 ins. under the shelter deck and 10 ins. under the lower decks, is well packed with insulating material, granulated cork, silicate cotton, or charcoal.

The bulkhead insulation follows the same form of construction generally with 8 ins. to 12 ins. of insulating material, not including the wooden sheeting. Insulated hatches are packed with

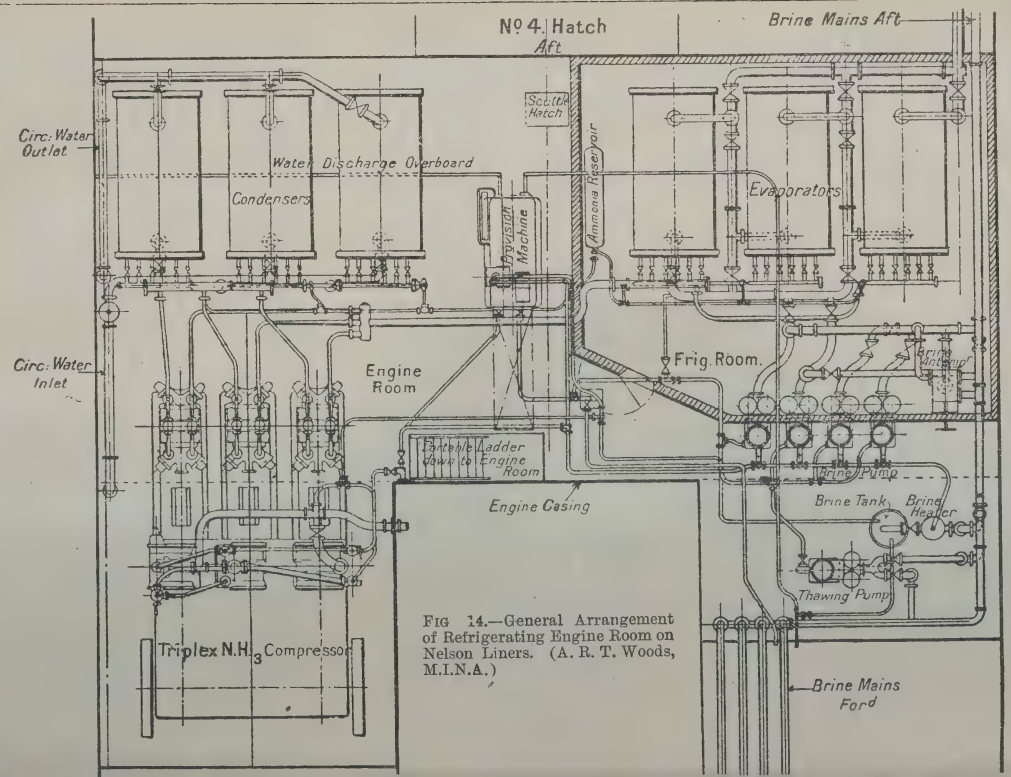

FIG 14.—General Arrangement of Refrigerating Engine Room on Nelson Liners. (A. R. T. Woods, M.I.N.A.)

cork or hair felt. The stanchions, pillars in holds, ventilating, sounding and thermometer pipes are insulated with 6 ins. of granulated cork covered with P. T. & G. boards. The beam brackets projecting inside the insulated space are covered with an inch thickness of hair felt in a casing of inch boards.

Arrangement and Temperatures of Chambers.

The *brine pipes* on ceiling, as well as the meat rails, are supported on channel bars suspended from the beams by bolt hangers. These brine pipes and rails are secured in position on the channel bars by clips, and insulated from the channel bars and clips with cork. The general allowance of brine piping is one square foot of surface of pipe to 8 cubic feet of chamber capacity.

The meat rails are placed about 12 ins. apart centres, and run fore and aft the entire length of the chamber.

The chambers over the decks are from 6 to 7 ft. in height, clear, between the floor and meat rail; each quarter of beef occupies approximately 10 cubic feet of space. The holds arranged for the carriage of chilled beef are generally from 13 to 15 ft. in height, the meat being hung in tiers of two or more quarters with long hooks or chains.

For the carriage of frozen meat where the carcases are stowed in tiers one over another, the holds ought not to exceed 20 ft. in height, in order to prevent the crushing of the lower tiers by the weight of those above. The lowest tier rests upon 3-in. by 3-in. battens placed athwart ship spaced about 12 ins. centres; battens about 2 ins. square are also placed vertically about every 12 ins. on the sides of the holds so that the cooled air may circulate between the insulation and the meat. The temperature of a chamber containing frozen meat should not be allowed to rise above 23°F. and is usually maintained at from 15° to 18°F.

Chilled meat chambers are kept at a temperature fixed generally between 28° and 30°F. The meat usually arrives on board with a temperature of 32° to 40°F., so that an amount of refrigeration has still to be done on the meat after stowage on board; this together with experience in connection with the quality of the meat, its treatment in the factory, and the estimated length of voyage are factors on which the choice of the temperature is based.

Butter is usually carried at 15° to 18°F. Fruit is carried at temperatures ranging from 33° to 50°. The temperature suitable between these limits and success in its conveyance is dependent upon the condition of the fruit when gathered, the care taken to avoid breaking or bruising the skin, the ripeness, the care bestowed upon the packing, wrapping and stowage on board, and also upon the estimated duration of voyage.

LLOYD'S RULES AND REGULATIONS RELATING TO REFRIGERATING MACHINERY AND APPLIANCES.

(*Abstract.*)

1. The insulation must be sound and in good order and of efficient construction. The details of construction showing the amount and nature of the insulating material employed in the various parts are to be reported to the Committee.

Bilge suction and sounding pipes and ballast tank air and sounding pipes, passing through insulated spaces, should be well insulated to prevent their being frozen up. No sluice valves, scuppers or drain pipes are to be fitted which will permit drainage from spaces outside of the insulated chambers into the bilges of the insulated holds.

It is recommended that the woodwork of the insulation over tunnel tops be fastened with screws to facilitate the examination of this part, and that extra strong battens of American elm be fitted upon it under the hatches. Insulated removable portions are to be arranged in the bulkhead insulation, where required, to give easy access to sluice valves and bilge suction roses. The bottoms, sides and coamings of all insulated hatches and limbers should be painted to prevent decay.

Thermometer tube flanges and covers should be arranged so that water does not run down and freeze in them when taking the temperature.

Cargo battens should be provided for the floor or deck and the sides of the chambers previous to loading the homeward cargo. Those for the sides of the chambers should be fastened, and should be at least 1½ in. in depth, and 2 ins. wide, one batten being placed over each frame or ground, the others being intermediately arranged. The battens for the floor and decks should be at least 2 ins. by 2 ins.

Where the brine system of refrigerating is employed, the brine circulating pipes and tanks should not be galvanised on the inside.

In cases where internally galvanised tanks and cooling pipes have been fitted, the brine cooling and return tanks, if closed, should be provided with two ventilating pipes communicating with the atmosphere. If the tanks are not closed, the cooling room should be efficiently ventilated.

2. The refrigerating machinery is to be of approved construction and of sufficient power to maintain the necessary low temperature in the cargo chambers in tropical climates when running 18 hours per day. For cargo capacities of above 70,000 cubic feet the machinery is to be either duplex or in duplicate.

LLOYD'S RULES, ETC., RELATING TO REFRIGERATING MACHINERY—*continued.*

3. A sufficient amount of spare gear is to be supplied and stowed where it is readily accessible.

No spare gear will, however, be required in cases where two complete sets of refrigerating machines are fitted, *each* being of sufficient power to maintain the necessary low temperature in the cargo chambers in tropical climates when running 18 hours per day, provided all the working parts of these machines are interchangeable.

When two similar machines are fitted, each connected to different cargo compartments, one set of spare gear suitable for either machiner will suffice.

WHERE ONE SINGLE DRY AIR MACHINE IS FITTED TO EACH COMPARTMENT, THE FOLLOWING WILL BE REQUIRED :—

1 crank shaft with eccentric sheaves, complete, or one half shaft if the halves are interchangeable.
1 piston rod and nuts for steam and air cylinders.
1 set of piston rod and connecting rod brasses.
1 piston, complete, for each steam and air cylinder.
1 cylinder cover for each pattern used in steam and air cylinders.
1 air pump bucket and rod.
1 circulating pump bucket and rod.
1 pair main bearing brasses, complete.
Main and cut-off valves for each steam cylinder.
Balance springs and rings for steam and air slide valves.
False valve face for each pattern fitted in steam cylinders, with screws.
1 eccentric rod for each pattern used.
1 eccentric strap for each pattern used.
1 slide valve spindle and nuts for steam and air cylinders, for each pattern used.
2 main bearing bolts.
1 set of connecting rod and piston rod bolts.
Full set of air valves and seats for air compressor.
1 set of inlet and outlet valves and 1 set valve faces (if fitted) for air expansion cylinder, with screws.
1 set of valves for air, circulating, and feed pumps.
1 set of escape valve springs.
50 suction springs.
50 delivery springs.
50 buffer springs.
6 tubes and 24 ferrules for condenser.
6 tubes for cooler.
6 tubes for air-drying chamber.
Assorted bolts, studs and nuts.
1 set of lead lined nuts for air expansion cylinder cover.
A quantity of packings and joint rings.

WHERE ONE DUPLEX OR TWO SINGLE DRY AIR MACHINES ARE FITTED TO EACH COMPARTMENT THE FOLLOWING WILL BE REQUIRED :—

1 crank shaft with eccentric sheaves complete, or one half shaft if the halves are interchangeable.
1 piston rod and nuts for steam and air cylinders.
1 set of connecting rod and crosshead brasses.
1 piston for h.p. steam cylinder.
1 piston, complete, for air compressor ; and 1 for air expansion cylinder.
1 set of piston springs for each steam cylinder.
1 cylinder cover for each pattern used in air compression and expansion cylinders.
1 air pump bucket and rod.
1 circulating pump bucket and rod.
Main and cut-off slide valves and spindles with nuts complete for h.p. steam cylinder.
Balance springs and rings for steam and air slide valves.
1 h.p. steam cylinder valve and valve face with screws.
1 eccentric sheave, strap, and rod for each pattern used.
1 slide valve spindle and nuts for steam and air cylinders for each pattern used.
2 main bearing bolts.
1 set of connecting rod and piston rod bolts.
Half set of air valves and seats for air compressor.
1 inlet and 1 outlet valve, and half set of valve faces (if fitted) for air expansion cylinder, with screws.
1 set of valves for air, circulating, and feed pumps.
1 set of escape valve springs.
20 suction springs.
40 delivery springs.

LLOYD'S RULES, ETC., RELATING TO REFRIGERATING MACHINERY—*continued.*

40 buffer springs.
6 tubes and 24 ferrules for condenser.
6 tubes for cooler and 6 for air drying chamber.
Assorted bolts, studs, and nuts.
½ set of lead-lined nuts for air expansion cylinder cover.
A quantity of packings and joint rings.

WHERE ONE SINGLE AMMONIA OR CARBONIC ANHYDRIDE COMPRESSION MACHINE IS FITTED :—

1 crank shaft with eccentric sheaves, complete, or one half shaft if the halves are interchangeable.
Piston and rods complete with nuts for each steam cylinder and gas compressor.
1 air pump bucket and rod.
1 circulating pump bucket and rod.
1 pair main bearing brasses, complete.
1 set of connecting rod and crosshead brasses.
Main and cut-off valves for steam cylinders.
1 valve spindle for each pattern used and nuts complete.
1 eccentric strap and rod for each pattern used.
1 brine pump complete.
1 cover for each pattern used.
2 main bearing bolts.
1 set of connecting rod and piston rod bolts.
1 set compressor suction and delivery valves with springs and boxes, complete.
1 set of valves for air, circulating, feed, and brine pumps.
Crank shaft for fan engine.
1 steam piston and rod, etc., for fan engine, complete.
1 pair of connecting rod brasses for fan engines, with bolts, etc., complete.
1 set of blocks for making all leather packings used.
6 tubes and 24 ferrules for condenser.
Lengths and bends of piping of each size used, together with flanges, couplings, and screwing apparatus for effecting repairs.
1 gas regulating valve.
1 distributing and 1 collecting piece with multiple branches for coils for each pattern used. If these pieces are made of forged steel, no spare pieces are required.
Sundry valves, cocks, flanges, and fittings.
Assorted bolts, studs, and nuts.
Quantity of leather packings and joint rings.

FOR AMMONIA AND CARBONIC ANHYDRIDE COMPRESSION MACHINES, THE FOLLOWING SPARE GEAR WILL BE REQUIRED, WHERE ONE DUPLEX OR TWO SINGLE MACHINES ARE FITTED TO EACH COMPARTMENT :—

1 crank shaft, or one half shaft if the halves are interchangeable.
1 steam piston rod and nut for each pattern used.
1 piston for h.p. steam cylinder, with springs, complete.
1 set of piston rings for each steam cylinder.
1 set of piston rings for each size of compressor.
1 compressor piston rod and nuts, complete, for each pattern used.
1 air pump bucket and rod.
1 circulating pump bucket and rod.
Main and cut-off slide valves for h.p. steam cylinder.
Main and cut-off valve spindles and nuts for h.p. steam cylinder.
1 eccentric sheave, strap, and rod, for each pattern used.
1 brine pump complete.
1 cover for each end of gas compressor, except where screwed plugs are used.
2 main bearing bolts.
½ set of connecting rod and piston rod bolts.
½ set compressor suction and 1 delivery valve with springs and box, complete.
1 set of valves for air, circulating, feed, and brine pumps.
1 steam piston and rod, etc., for fan engine, complete.
1 pair of connecting rod brasses for fan engines, with bolts, etc., complete.
1 set of blocks and leather for making all leather packings used.
6 tubes and 24 ferrules for condenser.
Lengths and bends of piping of each size used, together with flanges, couplings, and screwing apparatus for effecting repairs.
1 gas regulating valve.
1 distributing and 1 collecting piece with multiple branches for coils for each pattern used. If these pieces are made of forged steel, no spare pieces are required.

LLOYD'S RULES, ETC., RELATING TO REFRIGERATING MACHINERY—*continued.*

Sundry valves, cocks, flanges and fittings.
Assorted bolts, studs and nuts.
A quantity of joint rings.

In cases where an independent circulating water pump is used, and its work *cannot* be performed by the main or auxiliary engines, a duplicate pump complete should be fitted.

In cases where an independent circulating water pump is used, and its work *can* be performed by the main or auxiliary engines, a pump bucket and rod should be carried, and ½ set of valves for water end.

In cases where an independent surface condenser with air, circulating, and feed pump combined is fitted, and its work *cannot* be performed by the main engines :—

1 crank shaft with eccentric sheaves complete.
1 piston and rod complete for each pattern used.
1 eccentric strap and rod complete for each pattern used.
1 slide valve and spindle complete for each pattern used.
1 pump bucket and rod complete for each pattern used.
1 set of connecting rod and piston rod bolts and nuts.
1 set of valves for air, circulating and feed pumps.
6 condenser tubes and 12 ferrules.

In cases where an independent surface condenser with air, circulating, and feed pumps combined is fitted, and its work *can* be performed by the main engines :—

1 pump bucket and rod complete for each pattern used.
1 set of connecting rod and piston rod bolts and nuts.
½ set of valves for air, circulating, and feed pumps.
6 condenser tubes and 12 ferrules.

CONVERSION FACTORS.

Calories × 3·96 = B.Th.U.

Radiation—air contact transmission.

(Calories per sq. metre, per hour, 1° C. temp. diff.) × 4·91 = B.Th.U. per sq. ft., per 24 hours, 1° F. temp. diff.

Heat calories per kilogram × 1·8 = B.Th.U. per lb.
Atmospheres × 14·7 = lbs. per sq. inch.
Kilograms per sq. centimetre × 14·22 = lbs. per sq. inch.
Kilograms per sq. metre × ·2048 = lbs. per sq foot.
Cubic metres per kilogram × 16·06 = cubic feet per lb.

'Pulsometer' Refrigerating Plants.

The Pulsometer Engineering Co., Ltd., build apparatus for use with various refrigerants. They chiefly employ the anhydrous ammonia (NH_3) principle, as this medium renders the machine extremely easy to handle, and only requires a moderate working pressure; moreover, by the special construction of the fittings they use, which are made of forged steel cut from the solid, the loss of refrigerant is very small.

The Pulsometer Co. has also made a large number of machines on the CO_2 principle, for which system they are prepared to quote if an intending purchaser desires it.

SECTION XXIV

PART I

HYDRAULICS—GENERAL DATA OF WATER—WATER PRESSURE—HORSE POWER REQUIRED TO PUMP WATER—PRESSURE IN HYDRAULIC MAINS—DIMENSIONS AND STRENGTH OF HYDRAULIC PIPES AND CYLINDERS—PIPE UNIONS AND JOINTS.

General Data Regarding Water.

An imperial gallon of water at 62° F. weighs 10 lbs. avoirdupois. (See also page 208.)

Gallons multiplied by 277·420 = cubic inches. (*International Bureau of Standards, Paris.* 1921).

Gallons multiplied by ·16055 = cubic feet.

Cubic feet multiplied by 6·2288 = number of gallons.

Cubic inches multiplied by ·0036047 = number of gallons.

Cubic feet of water × 62·288 = number of lbs. weight.

Lbs. of water multiplied by ·016053 = cubic feet.

Gallons of water × ·004464 = number of tons.

Tons of water × 224 = gallons of water.

Cubic feet of water × ·027807 = number of tons.

Tons of water × 35·962 = cubic feet of water.

A pipe one yard long holds approximately (actually, 1·52 per cent. less) as many lbs. of water as the square of its diameter in inches; thus, a 6-inch pipe holds approximately 36 lbs. of water in each yard length.

Water-Pressure.

If

H = head of water in feet; P = lbs. pressure per square inch,

$$H = P \times 2{\cdot}311. \qquad P = H \times {\cdot}4326.$$

10 feet head of water gives a pressure of 4⅓ lbs. per square inch, approximately.

27·71 inches of water gives a pressure of 1 lb. per square inch.

TABLE SHOWING WATER PRESSURE CORRESPONDING TO VARIOUS FEET HEAD.

(*H. R. Kempe.*)

Horse-power required to Pump Water.

1 H.P. indicated will raise about 3,000 gallons of water per hour 50 feet high.

To pump 1 gallon of water per minute against a pressure of p lbs. per square inch requires $p \times \cdot0007$ H.P.

Allowing 40 per cent. for friction, the following shows the H.P. required to pump 1 gallon of water per minute at various pressures :—

Pressure per square inch, in lbs.	500	700	1000	1200	1500	2000	2250	2500	5000
Horse-power	·49	·69	·98	1·18	1·47	1·96	2·21	2·45	4·90

The *cost of lifting* 1 ton 50 feet is, in the case of the London Hydraulic Power Company, sometimes as low as $\frac{1}{4}d$.

Speed of Water should not, as a rule, exceed 100 feet per minute with 700 lbs. pressure. In the mains of the London Hydraulic Power Company the delivery is 1,040 gallons per minute, at a velocity averaging 2·83 feet per second, or 170 feet per minute. The loss of head due to this velocity is 22·896 feet per 1,000 yards, by the formula :—

$$\frac{(\text{Gallons per minute})^2 \times \text{length of pipe in yards})}{(3 \times \text{diameter of pipe in inches})^5}$$

The most distant point of the main is 5,320 yards, or just over 3 miles, from the accumulators. In a circuit of 5 miles the normal difference of pressure, or loss of head, was 20 feet head.

Pressure in Hydraulic Mains.

The average working pressure is 700 lbs. per square inch with accumulators, but varies from 300 to 1,500 lbs. per square inch. The pressure in the mains of the London Hydraulic Power Company averages 700 lbs., the actual pressure at the accumulators being 750 lbs.

700 lbs. per square inch = 549·78 lbs. per circular inch, equivalent to a head of 1,618 feet.

EFFECTIVE PRESSURE WITH 700 LBS. AT ACCUMULATOR.

Ratio of multiplying power . .	2 to 1	4 to 1	6 to 1	8 to 1	10 to 1	12 to 1	14 to 1	16 to 1

External diameter in inches .	$\frac{3}{4}$	1	$1\frac{1}{8}$	$1\frac{1}{4}$	$1\frac{3}{8}$	$1\frac{1}{2}$	$1\frac{5}{8}$	$1\frac{3}{4}$	$1\frac{7}{8}$	2	$2\frac{1}{8}$	$2\frac{3}{8}$	$2\frac{3}{4}$	$3\frac{1}{8}$	$3\frac{9}{16}$	$3\frac{15}{16}$	$4\frac{1}{4}$	$5\frac{1}{8}$
Number of threads per inch . .	14	14	14	11	11	11	11	11	11	11	11							

(1)

The external diameter, D, may be calculated from the formula :—

$$D = d\left(\frac{p}{f} + 1\right),$$

where,

d = diameter of bore of pipe, in inches ; p = pressure, in lbs., per square inch ; f = 4.000 for wrought iron, and 1,200 for cast iron.

(2)

$$T = \frac{(P + 100)\,D}{0{\cdot}4\,S} + 0{\cdot}333\left(1 - \frac{D}{100}\right),$$

where,

T = thickness of pipe in ins.; D = interior diameter of pipe in ins.; P = pressure of water in lbs. per sq. in.; S = ultimate tensile strength of cast-iron in lbs. per sq. in. (taken as 18,000 lbs.).

This formula gives the weight and thickness for good, tough, and elastic cast-iron pipes, covering the ordinary range of static pressures of public water supplies.

TABLE CALCULATED FROM FOREGOING FORMULA.

Head of water in ft.	115	150	200	250	300

60	1·35	1·50	1·70	—	—

(*R. D. Wood & Co., America.*)

(3)

$$T = \frac{(P + L)\,R}{3{,}300} + 0{\cdot}25.$$

where

T = thickness of pipe in ins.; P = static pressure in lbs. per sq. in.; R = inside radius of pipe in ins.; L = pressure in lbs. allowed for water hammer; 0·25 = a constant allowance for inequality in manufacture, deterioration, and rough handling; 3,300 = one-fifth of the tensile strength of cast-iron, which is taken to be 16,500.

The values of L—the allowance for water hammer—for different sizes of pipe are as follows, the allowance decreasing as the diameter and thickness of pipe increase :—

Diameter of Pipe, Ins.	Value of 'L,' Lbs.	Corresponding Head, Ft.
3, 4, 6, 8, or 10	120	277
12 or 14	110	254
16 or 18	100	231
20	90	208
24	85	196
30	80	185
36	75	173
42, 48, 54 or 60	70	162

For a static pressure of 100 lbs. per sq. in. a 6 in. pipe need be only 0·10 in. thick. Such thin pipe, however, could not well be made or handled, and allowance must be made (as above) for shock due to water hammer, for roughness in handling, for inequality in manufacture, and for deterioration. (*D. Fitzgerald, America*).

Thickness of Hydraulic Cylinders.

If T = thickness of metal in inches, P = bursting pressure in lbs. per square inch, R = radius of cylinder in inches, and C = constant (16,000 for cast iron, 34,000 for brass, 50,000 for wrought iron, and 70,000 for steel),

$$T = \frac{PR}{C - P}.$$

If D = external diameter of cylinder in inches, and d = internal diameter in inches, P and C being as above, then

$$D = d\sqrt{\frac{C + P}{C - P}}.$$

Strength of Hydraulic Cylinders

If f = allowable stress in lbs. per sq. in. ; P = working pressure in lbs. per sq. in. ; d = inside diameter in ins. ; D = outside diameter in ins. ; then

$$D = d \times \text{anti-log}\left(\frac{P}{p} \cdot 4343\right). \qquad (Clark.)$$

EXAMPLE.—If P = 3,000 lbs. per sq. in. ; f = 8,000 lbs. per sq. in. ; d = 30 ins. ; then

$$\frac{P}{p} \cdot 4343 = \frac{3,000}{8,000} \cdot 4343 = \cdot 16280 ;$$

anti-log.* of $\cdot 16286 = 1 \cdot 455$ (page 85) ;

therefore $D = 30 \times 1 \cdot 455 = 43 \cdot 65$ ins.

Size of Hydraulic Mains.

The largest mains used for hydraulic purposes are 7½ inches in diameter. The working stress on the metal due to working pressure is 2,800 lbs. per square inch. The mains are usually tested to a water-pressure of 2,500 lbs. per square inch before laying, and to a pressure of 800 to 1,600 lbs. per square inch after laying.

Pipe Unions and Joints.

For wrought-iron pipes up to 2 inches in diameter, such as are used for the connecting-pipes to hydraulic machines, the unions are generally of brass, and of the form shown by fig. 1. For

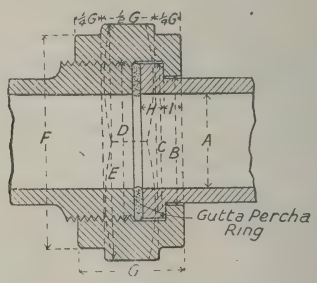

FIG. 1.

main cast-iron pipes the unions are made by means of elliptical flanges (fig. 1) formed on the ends of the pipes, the inner faces of the flanges being turned so that one pipe can enter a little distance into the other ; a recess is left between them, to receive a gutta-percha ring, whose outside diameter is about 4 times the inner.

Mains fitted with flanged joints of the description shown by fig. 2 can be made absolutely tight and free from leakage. The flanges are placed in a horizontal position in laying.

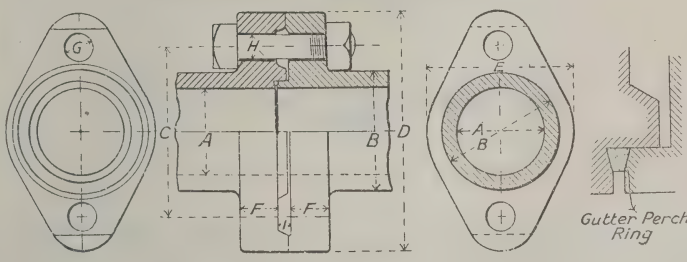

FIG. 2.

Mr. Ellington (engineer of the London Hydraulic Company) found that fractures in the pipes occurred by the breaking off of one of the bolt lugs. By placing the lugs a little farther back on the pipe the strength was found to be greater. It is probable that the slight flexibility of the pipe line which this kind of joint allows is an important element in its success.

On low-pressure hydraulic systems ordinary socket joints can be used.

In the *Philosophical Magazine* the Earl of Berkeley and Dr. Burton have described a simple form of joint packing, which is, they state, tight to start with and maintains this tightness up to the highest pressures they have employed, which have attained 1,500 atmospheres, or

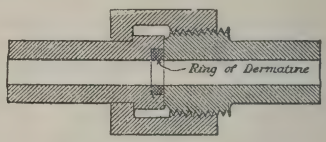

FIG. 3.

say, 10 tons per square inch. The pipe ends (fig. 3) are faced, and a recess is cut in one to take a ring of dermatine; this ring must be slightly thicker than the depth of the recess so that it is slightly compressed when the joint is tightened up. Either red or black dermatine may be used, but the red, being harder, is more easily machined. The joint is said to be equally good for water or oil, and is as suitable for a flanged joint as for a screwed coupling. It is also said to be as satisfactory with large pipes as with small.

THE VICTAULIC JOINT.

(*The Victory Pipe Joint Co., Ltd.*)

This joint (fig. 4) consists of a double 'U' washer or ring connected on the outside diameter by a bridge, but with 'inturned' lips—which exercise an initial grip on the pipe as it is placed in position. This feature of the joint renders it 'leakproof' against pressures, zero, and also under vacuum. The flexible leakproof ring, contained in a housing or shell, permits the provision of a small clearance between housing and pipe, so as to give slight angular flexibility,

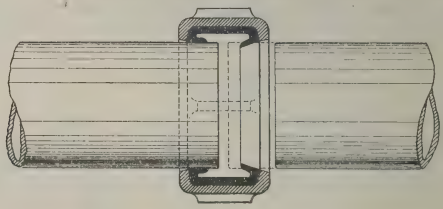

FIG. 4.—Victaulic Joint, 'A' Type.

hence subsidence or vibration has no effect on the leakproof qualities of the joint. The flexibility also allows for expansion: each individual length of pipe is free to expand separately. The arrangement of the joint affords a ready and quick means of 'breaking joint' for cleansing, the replacement of a section, the insertion of a junction piece. It is as easily dismantled as inserted, and occupies but little space. Two general types made are the 'Floating' A type (fig. 4), for pipe lines which are anchored, and the 'Location' B type, which positively prevents separation of the pipe, and does not interfere with its flexibility or expansion; it is used for high pressures and unanchored lines. The Victaulic leakproof ring is made of a material which is not affected by the liquids or gases passing through the pipes. For use on water-pipe systems the ring is made of the best rubber, which is very durable. For oil, benzine, and similar liquids, and also for chemicals, a special material, known as 'Victaulite,' is employed for the ring, which material is very durable, resists deterioration, and maintains an absolutely leakproof joint. A further development of the joint is its application to the stuffing-boxes of steam and water valves, the sealing effect being claimed to be far superior to that of the gland, and no adjustment is needed.

Cement Joints for Cast-Iron Water Mains.

(1.)

The pipe is placed and spaced in the usual manner. A thin backing of the best dry jute is used instead of oakum, as the jute is free from oil and grease, which should be avoided. Portland cement is placed dry on a piece of canvas (usually a cement sack ripped open) and moistened so that when thoroughly mixed by hand it will be of such a consistency that when gripped tight it will take the form of the hand and when dropped 12 ins. will crumble. The canvas containing the cement is placed under the bell, and the cement tamped into place by hand with a caulking iron until the bell is about half full. It is then caulked with heavy blows until the cement is thoroughly packed in the back of the socket. The process is continued until the bell is packed solid out to the face. A small bead of neat cement is then put on (this is essential), the caulking iron being used as a trowel, and, as soon as the initial set of the cement in the bead has taken place, the joint is covered with earth to protect it from the air and sun. In back-filling the excavated material is always settled with water, which helps to cure the exposed portion of the joint. The joint is allowed to stand forty-eight hours before the pressure is turned on and the main put into service. At Long Beach, California, there are now sixty miles of cast-iron water mains, ranging from 4 ins. to 24 ins. in diameter, laid with joints of this type. All these pipes are under pressures ranging from 40 lbs. to 80 lbs. per sq. in., and are giving satisfaction.

(*Clark H. Shaw, the American Society of Civil Engineers.*)

(2.)

A method of cement jointing cast-iron water pipes is described by Mr. G. W. Pracy in the *Journal of the American Waterworks Association*. The spigot end of the pipe projects into the bell just the same as for a lead joint, and two rings of jute or yarn are placed round the pipe and driven into the bell in the regular manner. The jute used must be free from oil or tar. Neat cement of standard Portland cement brand is used. The mix is very dry, the proportions being about 13 lbs. to 14 lbs. of cement to 1 lb. of water. The operator takes a handful of cement, and with an ordinary caulking iron forces the cement into the joint until full. He then takes a caulking hammer and caulks the joint until the cement is rammed in as hard as possible. The joint is then again filled and the operation repeated until the joint is completely filled with the rammed cement. At first a bead was put around outside the bell, but this was discontinued as being unnecessary. After the joint is finished it is covered with earth while the cement is hardening. In one case over a mile of piping jointed in this manner has been in use under 175 lbs. per square inch pressure for more than two years without requiring any repairs. It is claimed the method is cheaper than lead joints, and one indirect advantage is that the cement joint is an insulating joint, which tends to reduce damage from electrolytic action.

SECTION XXIV

PART II

PUMPS — STEAM PUMPS — PUMP PACKING — CENTRIFUGAL PUMPS—INTERNAL COMBUSTION PUMPS—AIR LIFT PUMPS.

PUMPS.

The surface of the water to be raised should not be more than 25 feet below the movable valve.

Especially for small pumps, the suction pipe of a pump should fall all the way from the pump to the supply well. Any upward bend in the suction pipe introduces an air trap and may seriously diminish the performance of the pump.

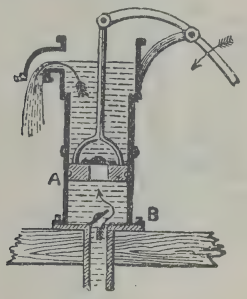

FIG. 1.

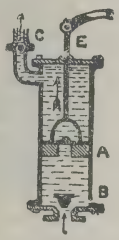

FIG. 2.

FIG. 3.

THE SUCTION PUMP.

This form of pump, which is shown by fig. 1, consists of a cylinder, called 'the barrel,' with valve, B, in which works a piston, A, called 'the box,' with valve in it, both valves opening upwards. The piston is attached to a rod and worked by a handle. When the handle is raised the piston is depressed: the valve A opens upwards, allowing the water or air below it to escape into upper part of cylinder. When the piston is raised the valve in it is closed, the water above is lifted up through the spout, the water from below lifts the valve at B, and rushes up to fill the vacuum caused by the raising of the piston.

If the valves are very dry a little oil should be poured on them. A little water poured on the piston before commencing to work it makes it air-tight.

LIFTING PUMP.

The suction pump is converted into a lifting pump by attaching a pipe in place of a spout at C (fig. 2), with a valve in it, opening upwards to prevent the return of the water. A stuffing-box is provided for the piston-rod to work in at E. Each time the piston, A, is raised the water above it is forced up the pipe, and, as the piston descends, the valve C prevents the return of the water from above. It is clear that the man who pumps must exert at each upward stroke of the piston as much strength as is necessary not only to raise a cylinder full from below, but also to lift the column of water in the pipe above.

The valve C is not necessary to the action of the pump, because, the barrel being full, the valve B retains all the water. It is used more as an additional check. The pump would also act if only valve C were in and B removed.

Single-acting Force Pump.

This form of pump, shown by fig. 3, is used to force up water to a height. The piston is made without a valve. The delivery pipe is at bottom of piston: it has a valve opening upwards at C to prevent the return of the water. When the piston is raised the valve B opens and the water rushes into the cylinder: when the piston descends valve B closes, valve C opens, and the water is forced up the pipe. In this pump the force is required for the down stroke. The top of the cylinder E need not be closed; a little water poured in above the piston makes it air-tight.

Plunger Pump.

Sometimes a solid plunger, A (fig. 4), is substituted for the piston, to avoid the expense of turning the cylinder true, and also because it resists better the wear from grease and dirt. At each stroke it raises a volume of water equal to that of the plunger.

Double-acting Force Pump.

This pump (fig. 5) sends up water both at the up and down stroke. At the up stroke the water above the piston is forced through the valve A, while that below enters the piston at the valve D; at the down stroke the water is forced through the valve C, whilst it enters above the piston at the valve B.

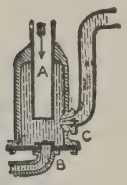

Fig. 4.

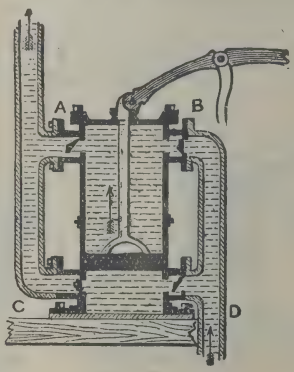

Fig. 5.

In all force pumps the packing of the piston or box is of great importance; it is commonly made of waste tow soaked in tallow and rammed tight; or for great pressures, cup leather packings are used.

Working Barrels, Buckets, and Valves.

These should be made of brass, gun-metal, or phosphor bronze, which metals, although costly in the first instance, will be found more durable, to require less repair, and to be more accurate in their operation than iron, being much less liable to injure the leather attached to the bucket and valve, the parts most frequently in want of repair.

An alloy which will withstand the action of water under pressure in a metal valve, and which is used by one of the largest firms in the country, consists of the following ingredients:—Copper, 10; tin, 1; zinc, $\frac{7}{8}$; lead, $\frac{1}{8}$.

The suction-pipe should be two-thirds the diameter of working barrel.

Pump Balancing.

To ensure equal work on the up and down strokes of a pump, it must be balanced. A complete balance provides for the whole weight of metal hung on the crank pin or beam, and one half the water work. The case of a bucket and plunger pump is perhaps the least simple, as in a bore-hole pump with a plunger at the surface delivering to a height above the surface.

Let A = area of bucket; a = area of plunger; W = weight of moving parts hung on crank pin and immersed in air; w = ditto immersed in water, e.g. the bucket and rods; H = height from water-level when pumping to plunger, in feet; h = height from plunger to point of delivery, in feet; B = balance weight to act at same lever arm as crank pin.

$$B = W + 0{\cdot}875\ w + 0{\cdot}216\ \{[A \times H] + [(A - a) \times h] - [a \times h]\}$$

The coefficient 0·216 represents one half the work, and the relation of pressure to head, or $0{\cdot}5 \times 0{\cdot}43$.

The correction for the different specific gravity of a gun-metal bucket may be neglected. Modern rods ultimately become as heavy as water, but at first have some negative weight. If a balance weight moves through a greater range than the cross-head, it must be correspondingly reduced.

Pumping from Wells.

For wells under 30 feet a 4-inch working barrel with a 9-inch or 10-inch stroke should be used. This size pump will throw 24 gallons per minute from a 20-feet well, and is as large as one man can conveniently work, and the best adapted for general use. For wells above 30 feet and under 70 feet a 3½-inch working barrel with a 9-inch or 10-inch stroke. For wells above 70 feet deep three 3-inch barrels, worked with a three-throw crank wheel and pinion in cast-iron case with fly-wheel, etc.

Artesian Well Pumps.

When the water level in a bore-hole is far below the surface, say 25 to 300 or 400 ft., it is necessary to place the pump barrel down the bore-hole, and it is usually desirable that it shall be lower than the rest level of the water, so as to be charged for starting work.

A bore-hole pump consists of a barrel of gun-metal with a bore at least 1 in. to 1¼ in. less than the diameter of the well lining tube. The barrel is screwed upon a rising main, which must be at least ⅛ in. to ¼ in. bigger than the barrel. The pump bucket and lower valve can thus be drawn up through the rising main for repair or inspection. A 4-in. pump will have a stroke of 1 to 3 ft. as desired, and a speed of 15 to 30 up strokes per minute. For durability it is desirable with very deep pumps to run at slow speeds. The pump rod terminates in a gun-metal rod or plunger, which passes through a stuffing box in the casting which forms the head of the pump. This head is flanged to the lining tube and screwed upon the rising main, and a branch is cast on one side for the water. If the lift above surface is considerable, it is possible partially or wholly to balance the lift of water to the surface by the use of a plunger, which may, if required, be as large in diameter as the bucket. However arranged, in order to equalise the work on the up and down strokes, it is proper to balance half the water lifting, and all the weight hung on the crank pin, so that the duty of the motive power may be evenly distributed in up and down strokes. Comparatively short pumps can be balanced by a weight in the main spur wheel on the crank shaft. When deeper, this is not sufficient, and a weighted lever may be linked to the crosshead pin and fitted with a balance weight on its outer or long end.

Some makers hang a heavy weight upon a pin in the face of the spur wheel, other makers attach wire ropes to the pump crosshead and pass them over a wheel and hang a weight, in guides, upon the ropes. Some engineers prefer to employ wooden pump rods, on account of their large displacement, so as to reduce the balance weights necessary.

A deep-well pump, unless small and slowly driven by a windmill, should be two to three diameters in length, of plain cylindrical form, with alternate grooves, with square-cut corners, and plain body. The grooves should be ½ in. × $\frac{1}{16}$ in. and the space between, $\frac{5}{16}$ in., the two extreme spaces about ⅝ in. to ⅞ in. No rings or packing leathers should be used.

The bucket valve may be mushroom, ball, or flat dermatine, the foot valve the same, in a taper casing, or foot piece which fits in the taper foot piece of the barrel. Under the bucket is a female screw which fits upon the thread projecting above the guard of the lower valve. When it is desired to remove the foot valve for inspection, it is lifted out by the bucket and pump rods, the bucket being lowered upon the valve and screwed to it; the valve then comes up with the bucket.

These pumps are usually driven from a second motion shaft by wheel and pinion, the second motion shaft carrying a fast and loose pulley driven by a belt from the engine or main shaft.

In country house work an oil-engine or an electric motor may be the driving agent, speed being reduced by more pairs of wheels or by larger driven wheels and pulleys. Or an electric motor may be worm-geared to the crank-shaft direct, in which case it is sometimes desirable to interpolate a friction clutch, so that the motor can be started off the load. Larger plants, such as the pumps for small town supplies, are perhaps best driven by gas-engines and suction gas plants.

Steel worms working in phosphor bronze wheels are said to give the best results. The wheel should be hollow faced so as partially to embrace the worm, and the angle of the teeth across the face of the wheel should be about 45°, so that the worm may require to be double or treble threaded to secure this. A thrust collar, or rather several collars, of propeller thrust type, are required on the worm shaft; but it is probably better to employ two worms, right and left, and two wheels connected to the same work, so that the thrusts balance, and no thrust block is required. The wheel should run in oil, which should be not too viscous. If a thrust block is employed, it should not be enclosed too narrowly, especially if near to the worm, as this has been found to prevent free access of oil.

When the water level in a bore-hole is not too deep below the surface, the air lift pump may be used with advantage, but it falls off in efficiency at great depths, and may often necessitate the boring of the well to depths very much greater than would be necessary merely to give the water yield. (*See also* Air Lift Pump, p. 1169.)

CAPACITY OF PUMP.

If d = diameter of barrel, in inches ; s = stroke, in inches ; n = number of acting strokes per minute ; g = gallons per hour ; then,

$$g = d^2 sn \div 6, \text{ approximately.}$$

Semi-Rotary Pumps.

THE WILLCOX SEMI-ROTARY WING PUMP.

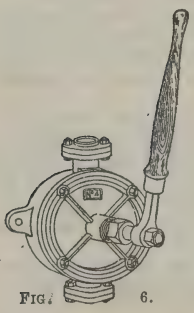

FIG. 6.

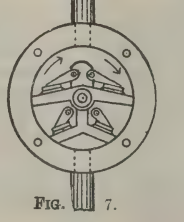

FIG. 7.

These pumps, figs. 6 and 7 (*W. H. Willcox & Co. Ltd.*), are made either double (as shown in the figs.) or quadruple acting. The working parts are of metal, and the wear and tear is reduced to a minimum ; they are claimed to be lighter and occupy less space than any other pumps of equal capacity, and are self-contained. Although fig. 6 shows a form for hand-working, these pumps are adapted for being fitted to any kind of motive power and can be employed for all general purposes.

The capacities in the foregoing table are based on 3 ft. suction, 3 ft. delivery, and on a full stroke; but the pumps will lift 25 ft. and force to a height of about 70 ft., according to size and speed.

'UBEL' SEMI-ROTARY WING PUMPS.

These pumps (*United Brassfounders and Engineers Ltd.*) have all parts made to standard limit gauges, ensuring absolute interchangeability. They are made either double or quadruple acting, the latter having a greatly increased capacity over the former. The capacities of the pumps given in the following table are theoretical, and based on a vertical suction of 3 ft. and a vertical delivery of 3 ft., with full stroke at the rate stated.

Double Acting.				Quadruple Acting.

" 10–12 are supplied with double handle.

For sandy or muddy water, residuary liquors, liquid manure, tar, etc., double-acting pumps fitted with ball valves are recommended.

Quadruple-acting pumps should be used in preference to double-acting when a large delivery is required in a short time without the application of considerable power.

Quadruple pumps are not made with ball valves, and should therefore only be used for clear liquids.

Special accessories, such as 'air vessels,' 'gauze strainers,' etc., can be supplied with the pumps.

The 'Chain Helice' Pump.

This pump consists of an endless chain, with sections of double open-wound wire helix arranged at short intervals over its entire length (fig. 8). This chain passes over a driving pulley at the top, and at the lower end is weighted by a heavy flanged pulley which rests in the loop of the chain, keeping it taut. This pulley should be submerged to the extent of about 2 ft. if possible.

Experiments have shown that the best results with clear water have been obtained with the chain running at a speed of from 400 ft. to 700 ft. per minute, according to the size of the chain. The capacity of the pump is affected by the height, the viscosity of the liquid, etc. The chain dips into the fluid in the well or container, the spirals become charged, and the fluid is carried up until the chain reaches the upper pulley, where it is discharged by centrifugal

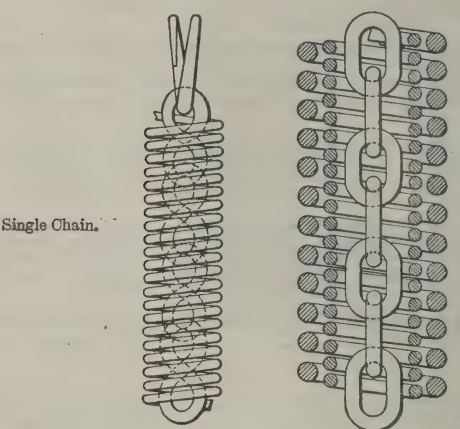

Fig. 8.

force into a receiver. In dealing with heavy liquids additional means are provided for removing the liquid from the outside of the chain, as centrifugal action alone is insufficient in this case. The losses on the upward path are mainly due to the slip of the fluid in relation to the chain. As, however, in falling, the fluid is constantly coming against the spirals of the chain, no great momentum is obtained, the mechanical efficiency of the device running out at about 50 per cent. It is calculated that between 70 and 80 per cent. of the water raised by the chain is delivered.

When in motion there is a tendency for the chain to wind, owing to the action of the spirals over the driving pulley. This is circumvented by introducing a swivel link in each chain, the standard chain length being 5 ft. Two sizes of chain are manufactured, viz. 31 mm. and 43 mm. With the latter size, which is a double spiral chain, and 3 ft. submersion and 30 ft. lift, a 1 h.p. engine driving a 'chaine helice' will deliver about 2,250 gallons per hour. With a 200-ft. lift a 5 h.p. plant will be required, and the delivery will be only slightly less, viz. 2,140 gallons per hour. With the single spiral, 31-mm. chain, the capacity ranges between 1,200 gallons and 1,150 gallons per hour, according to the lift, between 30 ft. and 200 ft., the horse-power needed ranging between 0·7 for the lower lift to 3·2 for the higher. Smaller pumps for hand operation deliver up to 150 gallons for 165-ft. lift.

The pump can be effectively used for clearing a well or trench if the bottom is sufficiently loose for the chain to score a groove in it without risk of the counterweight pulley becoming detached. A practical point in its application to deep well work is that all the work of installation is above ground, there being no fixtures down the well shaft, so that descent of the well is unnecessary. The installation of a unit is a matter of only one or two hours' work if a suit-

able platform at the well head is available. There are very few parts to get out of order, and the life of all parts is very good. The initial cost is about half that of other types of pumps. The upkeep is small, and the life a good deal longer than ordinary rotary or plunger pumps.

(*'The Engineer,'* April 27, 1920.)

STEAM PUMPS.

The Clarke, Chapman Direct-Acting Feed Pump.

(*Woodeson's Patent.*)

The single-cylinder direct-acting type of pump, on account of the small number of working parts and consequent small liability to break down, is very largely employed. Figs. 9 and 10 p. 1142, show Woodeson's 'Simple' Patent Direct-acting Pump (*Clarke, Chapman & Co. Ltd., Gateshead-on-Tyne*). This pump, which is extensively used, works with all steam pressures up to 400 lbs. per sq. in.

The steam chest is manufactured of the best hard close-grained cast-iron, of a suitable thickness to withstand any tendency to distort through the temperature of high-pressure steam.

The working parts of the steam chest consist of one auxiliary valve and one main valve, both of piston valve type.

The auxiliary valve is operated by the valve gear, actuated by the piston-rod crosshead. The main valve is partly moved mechanically and partly operated by steam, controlled by the auxiliary valve.

The action of the valves is as follows :—

When the main piston is nearing the end of its stroke, and the auxiliary valve commences to be moved by the valve gear, the first part of the movement closes the port through which the exhaust from one end of the main valve has been passing. The next part of the movement of the auxiliary valve opens steam to this end of the valve, and as the steam to the opposite end has not been closed, the main valve is in equilibrium. By the time that this takes place the auxiliary valve has moved so as to be in contact with the main valve, and further movement of the valve gear causes the auxiliary valve to move the main valve mechanically and so close the ports to the main cylinder. When these ports are nearly closed the auxiliary valve has closed the steam port at the end of the main valve, towards which the valves are moving, and opened an exhaust port, with the result that the main valve is moved by steam to the end of its travel and the steam cylinder ports are opened for the return stroke.

Should the main valve by any chance be delayed in being moved by steam, it would be worked mechanically during the clearance in the steam cylinder to a sufficient extent to open the steam port at the end of the cylinder towards which the piston was moving, and so forming a steam cushion to prevent the possibility of the piston striking the cover.

Advantages of the gear are :—

The main and auxiliary valves can all be mechanically actuated from the outside.

This is an advantage if the pump is standing for any length of time, as it keeps the faces from getting rusted up.

During the process of the mechanical movement, the piston to which this movement is imparted is in perfect equilibrium.

Entire absence of valve setting.

These pumps are also made on the Tandem Compound principle. Great economy has been obtained with the pumps, and they are specially applicable for electric power stations and other high-class installations where economy of steam is an important consideration.

Fig. 11, p. 1142, shows a pair of these pumps fitted with automatic controlling gear, as used for Main Independent Feed-Pumps for Marine Purposes ; with this automatic controlling gear there must be no dead points, and the pump must be able to start from any position, this being a special recommendation for a feed-pump for marine purposes, where, in order to derive all the benefits to be gained by using independent main feed-pumps, the speed of the feed-pumps must be automatically regulated according to the quantity of water to be dealt with, which varies with the speed of the main engines. The 'Woodeson' pump contains all the necessary features for this work.

No flat surfaces exist in any part of the water end exposed to pressure. Both suction and delivery valves are arranged in groups, and are easily accessible for overhauling. The plunger junks are of gunmetal, and are fitted with composition plunger rings, specially manufactured to deal with high pressure and high temperature.

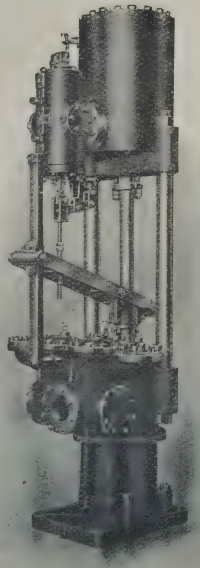

FIG. 9.

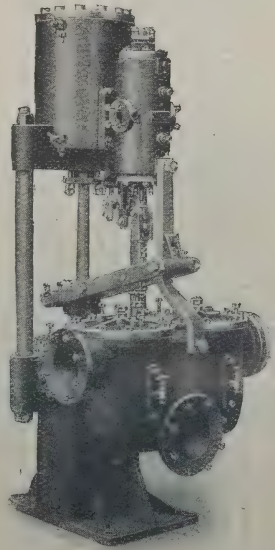

FIG. 10.

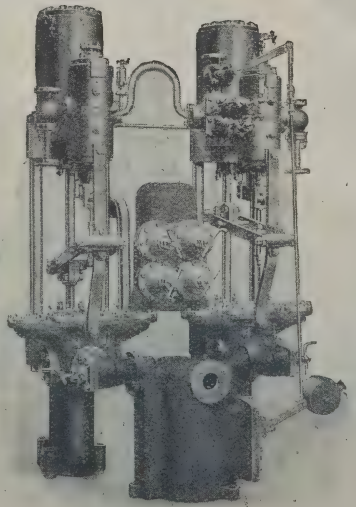

FIG. 11.

Test taken with Clarke, Chapman Simple Type of Slow Speed Feed-Pump (Woodeson's Patent) :—Diameter of steam cylinder, 10½ ins. ; Diameter of water cylinder, 8 ins.; Length of stroke, 18 ins. ; Water delivered per lb. of steam used, 81 lbs. ; Steam used per water h.p. hour, 59·5 lbs. ; Steam pressure per sq. in., 180 lbs. ; Pressure in discharge pipes per sq. in., 195 lbs. ; Efficiency of pump, 97 per cent.

Test taken with Clarke, Chapman Tandem Compound Type of Slow Speed Feed-Pump (Woodeson's Patent) :—Diameter of h.p. cylinder, 8¼ ins. ; Diameter of l.p. cylinder, 13 ins. ; Diameter of water cylinder, 8½ ins. ; Length of stroke, 18 ins. ; Water delivered per lb. of steam used, 110·5 lbs. ; Steam used per water h.p. per hour, 36·5 lbs. ; Steam pressure per sq. in., 195 lbs. ; Pressure per square in. in discharge pipes, 215 lbs. ; Efficiency of pump, 97 per cent.

The Caird & Rayner Single-Cylinder Direct-acting Boiler Feed and Service Pump.

The main and auxiliary slide valves of these pumps, figs. 12 and 13 (*Caird & Rayner*), are of the ordinary D type, and have flat wearing surfaces, and are therefore more easily understood and overhauled than those having circular slide valves, and are less liable to leakage. The pistons carrying the main slide valve are subject to end pressure only, so that there is no tendency to sticking, and the wear is practically nil. This obviates the necessity for re-boring worn parts of shuttle casing after working for a period, and the pump does not need to have an extra valve chest supplied as part of the spare gear. Should the water supply be suddenly stopped through any cause, the pump will not unduly race, nor will the piston strike the cylinder ends. The pump is silent in its working.

The main steam-valve admitting the steam to the cylinder ends is the ordinary D type, moving horizontally on a flat face. The auxiliary steam-valve which drives the main steam-valve is of the same type, and moves vertically also on a flat face. The main valve is separate from the small pistons which drive it, so that the pistons are subject to end pressure only, and the wear on them is practically nil. Any little wear on valve faces is taken up by the valves, and, being flat, all easily adjusted and refaced. The auxiliary valve face has ports which lead to the ends of the small cylinder carrying the pistons which drive the main valve. These ports are opened alternately to steam and exhaust, and throw the main valve from side to side. The auxiliary valve is actuated by a lever attached to a crosshead on the pump piston rod. The main steam ports are cast some distance from the cylinder ends, and a small steam port to the extreme end of the cylinder is provided, so that the speed of the pump is reduced when approaching the end of each stroke, thus enabling the pump valves to settle quietly in their seats, and also preventing shock in the feed-pipes. This arrangement of ports also prevents the piston striking the ends of the cylinder should the water supply to the pump for any reason fail, a feature which is of great importance. The pump will start from any point, and the stroke can be adjusted in running by means of the double nuts on the lower valve spindle. The pump valves are arranged in groups, and consist of a number of small valves working on a gunmetal seat. The valves are guided in an overhead frame and have no projections into the seatings, thus permitting a free flow of water and avoiding any side wear in the seatings. The water piston is fitted with ebonite rings, and will run for long periods without adjustment.

The materials of which the various parts are constructed are as follows :—Steam cylinder—close grained cast iron ; steam piston—cast iron or steel, with self-adjusting packing rings ; pump end—close grained cast iron, fitted with gunmetal liner in barrel, or all gunmetal, as required ; piston and pump rods—cold-rolled manganese bronze ; pump bucket—gunmetal, fitted with ebonite packing rings, or as may be desired ; valves and seats—group type of special manganese bronze, working on a gunmetal seat ; columns—mild steel, polished ; valve motion gear—rods and levers of wrought steel, turned bright ; crosshead—gunmetal.

The standard pumps are made suitable for 200 lbs. per square inch boiler pressure.

The Weir Direct-Acting Feed Pump.

The Weir Patent Direct-Acting Feed Pump (*G. & J. Weir, Ltd.*), shown in fig. 14, p. 1146 is the original of a type of pump which is being largely used. Introduced at first for marine boiler feeding, its adoption by the mercantile marine, the British Navy, and numerous foreign navies, caused it afterwards to be placed on the market in a form suitable for land installations, power plants, etc.

The valve gear is positive—i.e. the steam valve can never be in such a position that the pump will not start immediately when steam is turned on. The only possible way in which the main valve can rest is at full travel, either for an up or down stroke of the piston. The valve arrangement also ensures constant length of stroke and certainty of action.

WORTHINGTON

Special Purpose Pumps.

SHOULD the duty for which you require a pump appear to be a little off the beaten track, you can come to Worthington-Simpson's with confidence.

The wide variety of Worthington Pumps available makes it possible in most cases to select a standard pump for the work.

In any case, the valuable accumulated experience of our pump engineers is at your disposal for efficiently designing a new pump should the purpose necessitate it.

F. 1145

The steam valve is practically a D slide-valve, with a small auxiliary valve working on the back, and hence has not the same liability to leak as a piston valve. These are the only two moving parts proper in the steam chest, so that there is little opportunity for wear, and no delicate adjustments to get out of order. The steam is used expansively, and the cut-off can be regulated from the outside while the pump is working.

The water valves are of the Weir group type, providing a large area with only a small lift, thus ensuring easy working and little wear and tear. The pumps are designed to work at a moderate speed and the piston is slowed down towards the end of the stroke enabling the valves to settle quietly in their seats. The working and maintenance of the pumps is therefore much more satisfactory than in pumps running at a high speed. In the matter of steam consumption, numerous tests and comparisons show that the Weir pump is highly economical; this is due to the fact that it has fewer ports and passages than a duplex pump, and the simple expansion arrangement enables it to be built so that the clearance is small.

The parts of each pump are of a standard size, made to gauge and interchangeable, and each complete pump is tested hydraulically and under steam before leaving the works.

Where it is desired to regulate the boiler feed automatically, a special design of float tank and regulating gear is furnished.

The Weir pumps are also supplied of the tandem compound and twin compound types.

Messrs. G. & J. Weir, Ltd., Cathcart, Glasgow, the makers, also list a line of these pumps for light service, tank duty, etc.

List of Parts.—(See fig. 14.)

1. Steam slide valve chest.

The Warner Anthony Pump.

This pump, manufactured by *Robert Warner & Co.* (*Engineers*), *Ltd.*, 14/16 *Cockspur Street*, *London, S.W.*, is a distinct departure from the usual steam-operated gear fitted to most direct-acting steam pumps. The main difference lies in the fact that the whole of the working parts are self-contained and form a separate patented unit, which can be removed from, and replaced in, its valve chest by simply removing the steam chest cover, and without disturbing any adjustment. It is easily possible to shut down one of these pumps, take out the steam distribution unit, slip another unit in its place, and start up again, in five minutes. Pumps so fitted have run since the war under adverse conditions night and day for upwards of two years without a stop.

Fig. 15, p. 1148, represents a section through a steam cylinder and valve chest with the patented unit in its working position in the chest. The main cylinder has an ordinary three-ported valve face on which works an ordinary slide valve B. The unit proper which bridges over this slide valve, but which is quite separate from it, consists of a small cylinder provided with faces which contact with port faces on either side of the main port face of main cylinder. Inside the cylinder A is a piston C attached to a piston rod E which passes up through the unit cylinder cover and has on its outer or upper end a circular head F, which fits into a separately formed recess in a small cover G in the top of the valve chest, which recess is so arranged that whilst the head of the piston rod can be withdrawn horizontally, no vertical motion is possible.

It will thus be seen that the usual arrangement is reversed, in that the piston C is held in one fixed position, while the cylinder A is free to move on it.

Through the lower end of the valve chest works the valve rod H attached by lever gear to the main piston rod, a fulcrum being provided by a bracket bolted to a lug on the main cylinder casting. The rod H is, like the rod E, provided with an enlarged circular head J, which works inside the hooded recess K formed in the lower end of the unit cylinder A.

Supposing now that steam is admitted to the bottom side of the main piston, the top side being open to exhaust, the sequence of operations is then as follows:

The main piston travelling upwards pulls the rod H downwards; when the rod has travelled down a certain distance, the head J engages with the lower face of the recess K and thus pulls down the cylinder A, and with it the slide valve B. At the moment when the head J engages with the lower face of the recess K, two small ports, which are arranged one on either side of the slide valve B, but which are not shown in the figures, come into register with two other small ports in the cylinder A, also not shown. When the main piston has nearly completed its stroke, and when the lower main steam port has been closed by the valve B, the head J has pulled the cylinder A so far that the small port on one side has passed over the edge of the main port face, while at the same moment the small port in the other side is put into direct communication with the main exhaust port, the result being that live steam is admitted to the lower end of the unit cylinder A, shooting it over the remainder of its travel and carrying with it the slide valve B. This action opens the upper steam port MSP 1 of the main cylinder to the live steam in the valve chest, and puts the lower main port MSP to exhaust. The same sequence of operations is then repeated, the unit in this case being pushed up instead of being pulled down.

In the sectional view the main piston is shown on its downward travel. The valve rod H travelling upwards has just come into contact with the upper face of the recess K of the unit cylinder, and is about to carry it and the slide valve up with it, so shutting off the upper main steam port MSP 1, after which the unit will be shot over by steam pressure acting at the right moment on the upper side of the fixed piston, this shooting it over and reversing the main valve B.

This system is fitted by Messrs. Warner to pumps for all duties, and is supplied by them to the British and Allied Admiralties and the principal users of this type of machinery.

The Weir 'Roto-Feed' Pump.

This pump (*Messrs. G. & J. Weir, Ltd., Cathcart, Glasgow*), shown by fig. 16, p. 1149, consists of a single pressure, multivelocity stage, impulse steam turbine, working in conjunction with a single stage centrifugal pump of special design.

The turbine casing and bearings are divided horizontally, the lower portions being embodied in the general framework or base of the set. This framework is extended at one end to form a flange, to which the pump casing is rigidly secured. By this arrangement the impeller of the pump is carried on the overhanging end of the turbine shaft; absolute alignment and compactness are thereby secured and the necessity for a third bearing with its attendant complications is avoided.

The Rees Roturbo Mfg. Co. Ltd.

Hydraulic, Electrical and General Engineers,

Head Office and Works : **WOLVERHAMPTON, England.**

LONDON OFFICE : Hastings House, Norfolk St., Strand, W.C.

By means of a suitable hydraulic governor, operating a balanced double beat throttle valve, the set is self-regulating for all ordinary changes in both water and steam conditions. When the latter are decidedly adverse, auxiliary nozzles may be brought into play by means of auxiliary valves in the nozzle box and the quantity of steam supplied to the turbine considerably augmented.

An emergency governor of the eccentrically-loaded ring type is provided, which, in the event of the speed of rotation exceeding a predetermined limit, actuates a trip gear which releases a spring and instantaneously closes the stop valve, and steam is completely shut off from the turbine. Thus there is no possibility of the speed of the set reaching unsafe limits in the event of an accidental failure of the supply; and as the discharge pressure depends upon the pump speed only, the set cannot be seriously overstrained by sudden obstruction or closing of the discharge.

The turbine glands are provided with carbon packing, the bearings are of the self-oiling ring type, and the pump impeller is hydraulically balanced.

The Weir Roto-Feed Pumps are of sound mechanical construction and all parts are readily accessible for examination and overhauling. They are entirely automatic in action and are noiseless and free from vibration.

The pumps are capable of discharging against the highest boiler pressures and are specially

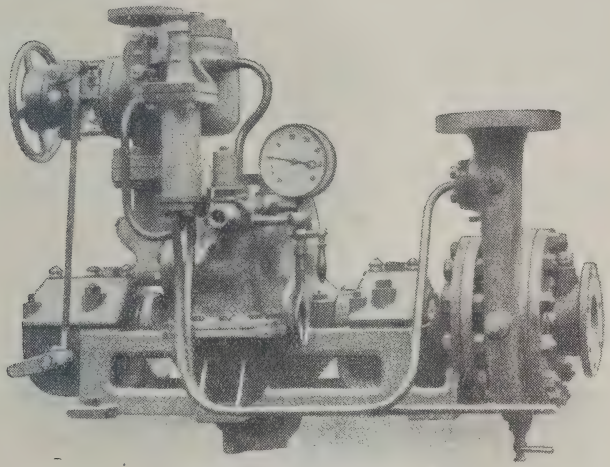

FIG. 16.—The Weir 'Roto-Feed' Pump.

suitable for large units. They can be used to work in conjunction with ordinary reciprocating pumps.

A special feature of the Weir Roto-Feed Pump is its economy in steam consumption. Further, as the exhaust steam contains no oily residue, it is available for heating the feed water by direct contact, thereby utilising all the heat in the steam. In this connection Messrs. Weir have introduced a nozzle heater which has been specially designed for working in conjunction with these pumps.

The Weir Roto-Feed Pump has been adopted by the British Admiralty and the leading Municipalities and Electric Power Corporations, including the Corporations of Cardiff, Glasgow, Greenock, Halifax, Norwich, Poplar, Salford, West Ham, Wolverhampton, Woolwich, the Clyde Valley Electric Power Co., and Treforest Electrical Consumers, Ltd.

Boiler Pressure Required for Pumping.

What boiler pressure would be required to operate a direct-acting steam pump having an 8-in. diameter steam cylinder and a 6-in. diameter water cylinder, for pumping water to a height of 100 ft. with the suction water supplied at a pressure of 10 lbs. per sq. in. ?

The mechanical efficiency of a pump of the stated size, when in good working order, would be about 65 per cent. The pressure pumped against would be $100 \times 0{\cdot}433 = 43{\cdot}3$ lbs. per sq. in. due to the head, plus the pressure required to overcome friction of the water in the discharge pipe, the latter depending on the rate of pumping, and the diameter length and fittings of the discharge pipe. Under ordinary conditions the loss of pressure from pipe friction would be no greater than 10 lbs. per sq. in., and if assumed to be equal to the suction pressure the net resistance to movement of the water piston would be $(6 \times 6 \times 0{\cdot}7854) \times 43{\cdot}3 = 1{,}224$ lbs. With 65 per cent. mechanical efficiency of the pump, the resistance to be overcome by the steam piston would be $1{,}224 \div 0{\cdot}65 = 1{,}883$ lbs., and for overcoming that resistance the effective pressure required to be exerted on a direct-acting 8-in. diameter steam piston would be $1{,}883 \div (8 \times 8 \times 0{\cdot}7854) = 37{\cdot}46$ lbs. per sq. in. The required boiler pressure will need to be equal to the effective pressure, plus the back pressure and the reduction of the boiler pressure by throttling in the steam pipe and steam passages of the pump. Allowing a back pressure of 4 lbs. and reduction by throttling of 10 lbs. per sq. in. would require a boiler pressure of $37{\cdot}46 + 4 + 10 = 51{\cdot}46$ or about 52 lbs. per sq. in. *(Power.)*

The Pulsometer Steam Pump.

In this pump (*The Pulsometer Engineering Co., Ltd.*), fig. 17, the neck J contains a gun-metal ball I, above which is a steam pipe K. EE are suction valves placed at the base of two chambers

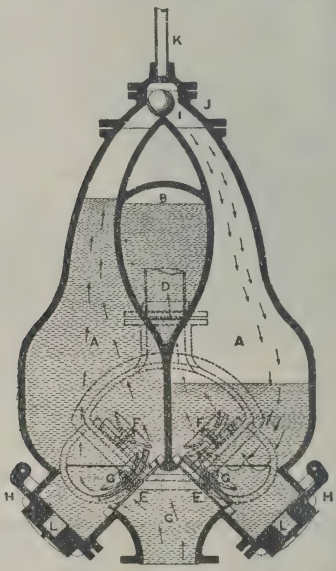

Fig. 17.—The Pulsometer Steam Pump.

AA, which communicate with a 'discharge box' and with an air vessel. Immediately above the suction valves the two chambers communicate with a 'discharge box' through two discharge

valves EE. The valves in the standard pattern of pump are of the grid type, consisting of a grid, rubber, and guard. In addition to the above valves there are three small gun-metal valves (not shown in the figure) for the admission of air, one of each being screwed into the upper part of the two water chambers and the air vessel.

Action.

Assuming one of the chambers to be open to steam and full of water, the steam entering by the steam pipe and past the ball passes into the chamber and presses upon the small surface of water exposed, and depresses it without agitation (and therefore with little condensation) and drives it (as seen in the figure) through the discharge valves into the rising main, D. The moment the water in the chamber falls to the level of the opening in the branch leading to the discharge box, the steam blows through with a certain amount of violence, and as it is brought into intimate contact with the water in the discharge box an instantaneous condensation takes place, and the vacuum thus formed in the emptied chamber immediately pulls the control ball over on to the corresponding seat and cuts off further admission of steam, allowing the vacuum to be completed. Water immediately enters through the suction pipe, and lifting the inlet valve rapidly fills the chamber again. A similar operation has been taking place in the fellow chamber, the period occupied by filling one chamber corresponding to that of emptying the other, and these operations continue alternately in the two chambers so long as the pump is supplied with steam and water. The function of the air valves is to introduce a small quantity of air at each stroke or 'pulsation' for the purpose of cushioning the ball when it changes its position, and for separating the steam from the water by a non-conducting film so as to prevent loss by condensation during the expulsive portion of the cycle.

The 'Pulsometer' Steam Pump will work just as well suspended from a chain or rope as when permanently fixed. Its very small size, in proportion to the quantity of water thrown, makes it available in a great many situations where no other pump can be applied, and another important feature is its ability to pump water heavily charged with mud and sand. For these reasons it is very largely used by contractors for pumping from excavations.

The 'Pulsometer' Steam Pump will, where the conditions remain constant work day and night without attendance—in fact, as long as steam and water are supplied to it.

WILLCOX-PENBERTHY CELLAR DRAINER.

This is a Water Pressure Ejector (*W. H. Willcox & Co. Ltd.*) of high capacity, for use in removing water from cellars, inspection pits, stokeholes, lift pits, or wherever it is desired to keep water or other liquids from rising above a certain level. It is automatically operated by a float-controlled, quick opening and closing valve. This valve is never partially opened; it cannot leak, and allows the ejector to give its greatest efficiency by working to full capacity. The float arm is slotted where it connects to the valve lever; this prevents the ejector from operating until the water has raised the float up to the highest point, and, as the water is ejected, the arm travels down the length of these slots before the weight of the float affects the valve.

To facilitate the installation of this drainer in small holes or sumps it is made as compact as possible. The float, instead of being round, is flat on the top; this gives it more buoyancy and occupies less space than would a round float of the same diameter. To further economise space the float is built around the suction pipe. This arrangement (patented) has the advantage of being rigid, and overcomes all the trouble of a loose float. The balance of the drainer is built directly above the float; this not only keeps the whole machine in as small a space as possible, but also keeps all working parts, with the exception of strainer and float, above the water, thus preventing corrosion or the exterior parts becoming clogged up by deposits of slime, dirt, or sediment. The interior parts are prevented from coming into contact with any foreign particles by a special strainer, which is so constructed that instead of the water being drawn directly upward, it is taken in at the sides, allowing all sediment to collect under the strainer without being disturbed by the force of the suction. A foot valve is provided inside the strainer, which closes the instant the drainer ceases operating, holding all water in the pipes, all primed for starting instantly at the next filling of the sump.

The following table shows the capacities at different pressures and elevations, dimensions, pipe sizes, weights, etc.:

Size No.	Working Head in Ft.	Actual Capacities in Gals. of Water per Hr. taken from Sump, and *not* Total Amount of Discharged Water. At 25 lbs. will Elevate	At 40 lbs. will Elevate	At 60 lbs. will Elevate	At 80 lbs. will Elevate	Pipe Sizes, in Ins. Supply.	Discharge and Suction.	Dimensions over all, in Ins. Height.	Diameter. 	12		670	1,280	1,440						

All sizes will also work with a head of 18 ft. and with 60 lbs. or 80 lbs. pressure.

Low-pressure patterns in Nos. 1 and 2 sizes for pressures 10 to 30 lbs., and elevations 4 to 10 ft.

Pump Valve Materials.

Dexine.

Dexine (*Dexine, Ltd.*) is a preparation of vulcanised indiarubber and other ingredients, manipulated by a special process; it is an exceedingly tough and frictionless material which has been proved to withstand the action of oils and chemicals. It is extensively used for valves, in the place of ordinary indiarubber, and can be obtained in any degree of hardness, suitable for straight or curved guards and pumps of all descriptions and of all dimensions.

Valves made of Dexine are claimed to retain all the resiliency and natural cohesion of pure Para rubber—which enters into its composition to a certain extent—and is, in addition, rendered immune from the detrimental influence of acids, oils, alkalies, or grease. The material can be moulded to any shape, and vulcanised to any degree of hardness or flexibility to suit any particular purpose.

Dexine is also used to form the 'bucket or cup leathers' of pumps, up to 20 ins. diameter. In round or square section, or in the form of U rings, the material makes an efficient packing for compressor rods, and, having a low coefficient of friction, the wear on the material is very slight.

Hydraulic Leathers.

Ram or 'U' Leathers.

A cupped leather packing (ram or 'U' leather) forms a self-tightening packing, and is very generally used, although if it is not properly made, and if the cup is not strengthened at the bend (where the greatest friction is), the leather soon wears out and fails.

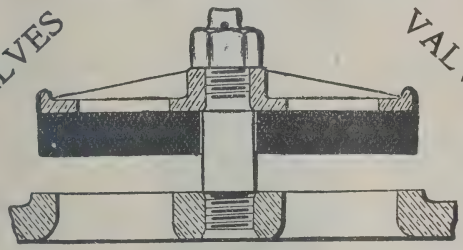

Fig. **18** shows a ram leather in its position.

The water gets behind the leather and presses it tightly against the ram; the friction occurs mainly at part A, and increases as the pressure of water increases. There is not much friction at the portion between A and B, and the efficiency of the press is but little altered by making AB greater or less. It is, however, asserted by some that the distance AB is of importance, but this is on account of deterioration. The part AB is constantly in states of tension and compression, and if the leather is not good and well made it is liable to crack. A shallow leather is undoubtedly the best. It works just as well as a deep one, and in making the leather considerably less strain or pull is required to block or mould it than would be the case with a deep one.

Nine Elms Iron Works,
READING

F. 1153

Leathers are very frequently made too deep, and this leads to their being more liable to crack and fail. Too much stress cannot be laid on the necessity for using leather packings of the best quality and make only. It is equally important to consider the question of tannage.

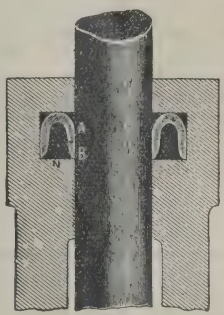

FIG. 18.

The value of a tannage depends upon its suitability and adaptability for different classes of work. Low pressure work, for example, requires a different tannage and fibre from high pressure, and medium pressure a tannage and fibre between the two.

NOTES ON HYDRAULIC LEATHERS.

Where dirty or gritty water has to be used the leathers wear away very rapidly. When the leathers are not kept constantly under pressure, if the pressure is taken off, the water gets between the leather and the ram, and as soon as the pressure comes on again, a little gritty or dirty water passes between the leather and the ram and causes the wear of the packing; it also scaives or flutes the ram. A remedy for this consists in putting a relief valve on the pipe that delivers the water to the accumulator from the pump, and in leaving the suction valve always open. The pressure in this way is always kept on the leather, preventing leakage, and at the same time saving considerable wear and tear of the packing.

Corrosion is one of the principal annoyances of hydraulic power, and bad water is responsible for fully 50 per cent. of wear and tear and repairs. Chalybeate water (that is, water containing iron) is about the worst.

For lubrication, Entwistle's patent lubricant, which contains a certain quantity of very finely-powdered metal, has given excellent results; the particles of metal, by the motion of the ram up and down, anneal themselves to any indentations, pores, or rough surfaces there may be on the ram or in the cylinder, and being of a soft or yielding nature (not gritty) distribute themselves over the rough surfaces.

It is important and essential that a leather should be well rubbed and worked with tallow before putting in. A good plan is to fill the inner space of the leather with neatsfoot oil or sperm about an hour before putting in. *Never use mineral oil for rams or cylinders*, it runs away quickly through being thin, and also renders the leathers rotten and pulpy.

Pump Packing.

A 'non-rot' self-lubricative packing (*Turner Brothers Asbestos Co. Ltd., Rochdale*) owes its properties to specially treated hemp yarn. A packing is also manufactured from a high quality flax cloth, in which is inserted anti-friction metal presenting a good surface to the rod; it is provided with a central core which gives a high degree of elasticity with a cushioning effect, bedding to the wearing surface of the rod. It is especially suitable for worn and scored rods. It is supplied in rings or in 12-ft. spiralled coils; sizes, $\frac{1}{4}$ in. and upwards.

LOSS OF POWER BY FRICTION.

The loss by friction in pumping into an accumulator packed with hemp has been found to range from 3 to 8 per cent. at 100 lbs. pressure; the difference of pressure during the rise and fall of the accumulator represents from 1 to 2 per cent. of the power. With leather packing the

friction varies with the diameter of the rams, or as to the square roots of the gross load. Neither the depth of the leather nor the length of the ram affects the total friction. Experiments give the following formula :—

$$F = \frac{P \times C}{D},$$

where F = total friction of leather packing, D = diameter of ram in inches, P = pressure per square inch, C = coefficient. C = ·0471 with new or badly lubricated leathers ; C = ·0314 with leathers in good condition and well lubricated.

The following table shows the frictional resistance in percentage of the total hydraulic pressure, for rams from 2 inches up to 20 inches in diameter :—

D ins.	F per cent.	D ins.	F per cent.	D ins.	F per cent.	D ins.	F per cent.
2	2·00	7	0·57	12	0·33	17	0·23
3	1·33	8	0·50	13	0·30	18	0·22
4	1·00	9	0·44	14	0·28	19	0·21
5	0·80	10	0·40	15	0·26	20	0·20
6	0·66	11	0·38	16	0·25		

$$F = \frac{0{\cdot}0416}{D} P \left\{0{\cdot}09347 - 0{\cdot}00000019291P\right\},$$

where F = friction in lbs., D = diameter of piston in feet, P = gross pressure in lbs. per square foot of piston area. (Correct up to about 1 ton per square inch.)

CENTRIFUGAL PUMPS.

V = velocity of the periphery of fan, in feet per second. H = height, in feet, to which water is to be raised. R = revolutions per minute of fan. D = diameter of fan, in inches. W = width of fan at the periphery, in inches. d = diameter of discharge-pipe, in inches. n = number of blades. t = thickness of blades. G = gallons per minute. E.H.P. = effective horse-power required.

$$V = 8{\cdot}8\sqrt{H}, \text{ for small fans, to } 10{\cdot}5\sqrt{H} \text{ for large fans.}$$

Another formula is—

$$V = 8{\cdot}8\sqrt{H} + K, \qquad \text{where } K = 5 \text{ to } 10.$$

The last formula gives good results, varying the coefficient K with the height of lift.

$$R = \frac{V \times 230}{D} = \frac{(8{\cdot}8\sqrt{H} + K) \times 230}{D}. \qquad D = \frac{(8{\cdot}8\sqrt{H} + K) \times 230}{R}.$$

$$D = 1{\cdot}5d \text{ to } 5d. \qquad d = \frac{\sqrt{G}}{4}. \qquad W = \frac{d^2}{4D - 1{\cdot}27nt}. \qquad \text{E.H.P.} = \frac{G \times 10 \times H \times \frac{5}{2}}{33000} = G \times H \times {\cdot}00076.$$

(The fraction $\frac{5}{2}$ represents 40 per cent. efficiency.)

EXAMPLE.—What size of pump is required to lift 4,000 gallons per minute to a height of 15 feet?

First find velocity, V, of periphery of fan. Taking 6 as a mean value for K, then $V = 8{\cdot}8\sqrt{15} + 6 = 34{\cdot}08 + 6 = 40{\cdot}08$ feet per second, or, say, 40 feet per second.

Diameter, d, of discharge-pipe at 4,000 gallons per minute, G, $= \frac{\sqrt{4000}}{4} = 16$ inches.

Taking $D = 3d$ as a mean value, then $D = 3 \times 16 = 48$ inches.

Number of revolutions per minute, R, $= \frac{40 \times 11000}{48 \times 48} = 191.$

Taking 6 blades (n), each having a thickness, t, of $\frac{1}{2}$ inch, then

$$\text{Width, W, of fan} = \frac{16 \times 16}{4 \times 48 - 1{\cdot}27 \times 6 \times \frac{1}{2}} = \frac{256}{192 - 3{\cdot}81} = 1{\cdot}36 \text{ inches.}$$

The greater the diameter of the fan, the less number of revolutions it requires to make.

The speed of the water through the pipes should not much exceed 8 feet per second. In many pumps the speed is greater (10 feet per second) ; but this is too high for good practice.

In all cases the efficiency of a pump will be increased by a tapering enlargement of the discharge pipe to as large a diameter as convenient. Such a taper pipe should be very slowly tapered, say about 1 in 8 times its initial diameter.

The best speed to drive centrifugal pumps is a much debated question. For mine use moderate speed is preferable wherever possible, as less trouble is then experienced with both pump and motor. In other cases the higher speed pumps give good service. For 75 or 100 h.p. and upward 900 r.p.m. is satisfactory; for 30 to 50 or 75 h.p. 1,200 r.p.m., and for smaller pumps 1,500 to 1,800 r.p.m. (*H. Axford in 'Coal Age.'*)

CLASSIFICATION OF CENTRIFUGAL PUMPS.

Generally speaking, centrifugal pumps may be classed in two groups, namely :—(*a*) Without guide wheels ; (*b*) with guide wheels.

(*a*) In pumps which are *not provided with guide wheels* (fig. **19**), the casing is constructed with a spiral-shaped channel with gradually widening sectional area, which acts as a diffuser. These pumps are usually termed low-lift and medium-lift centrifugal pumps, and have, as a rule, one—sometimes two—stages. The pressure they produce ranges up to about 300 ft. water column.

(*b*) For pressures above 300 ft., as required for hydraulic service, mine drainage, boiler feeding, waterworks, etc., three, four up to ten impellers are arranged in series and all built in the common casing (for extraordinarily high pressures two cases might be used).

With these high-lift pumps (fig. 20) the water passes through each impeller in turn, and is directed from one impeller to the next following and from the last into the delivery branch of the pump through specially designed *guide wheels*, converting into pressure, without shock, the bulk of the kinetic energy transmitted to the water by the impellers. Each stage of the pump contributes equally to the total pressure. The design of the diffuser guide wheels and the blades of the

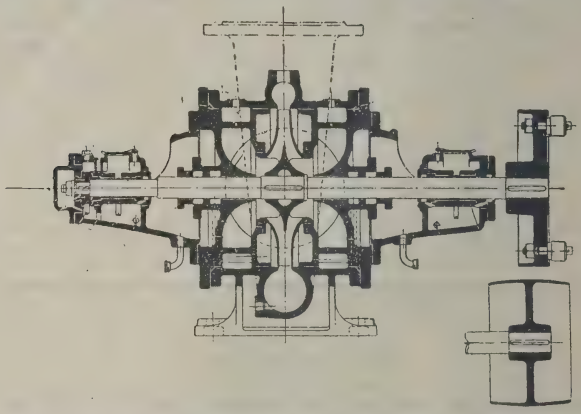

FIG. 19.—Section through Centrifugal Single-stage Pump (Low-lift or Medium).

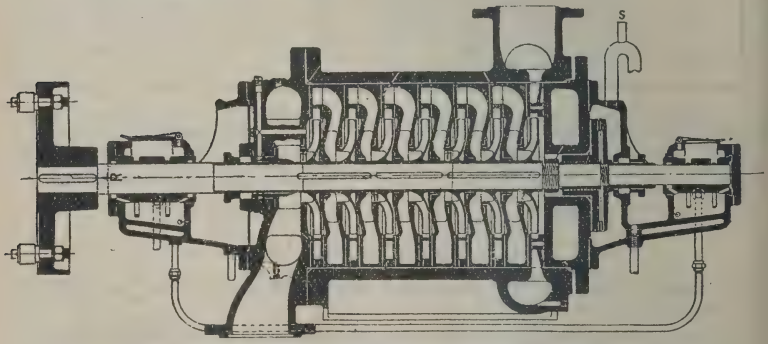
impellers, i.e. the passages through which the water travels with a high velocity, is mainly responsible for the degree of efficiency attained by a centrifugal turbine pump. The steady flow of water through the pump, with as few changes in velocity as possible, avoiding shocks and eddies with inherent friction loss, is of the greatest importance. The clearance between the rotating and stationary parts in the pump must be so dimensioned that too much water cannot



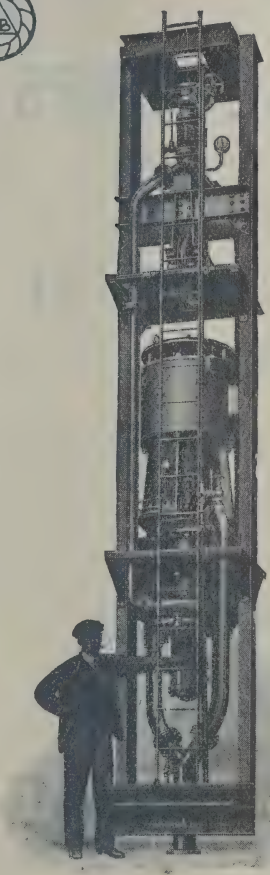


FIG. 20.—Section through Centrifugal High-lift Pump.

flow back from one stage to the preceding one. The balancing of the axial thrust produced in multi-stage pumps is also important.

There are practically no limits as regards the pressure heads that high-lift centrifugal pumps cannot overcome (some makers, for example, have supplied pumps delivering to 3,500 ft.), as long

as the quantity to be delivered is not too small. The manometric suction head should, for hydraulic reasons, not exceed about 18 ft., as otherwise the efficiency may be reduced and wear in the first stage be caused. For hot liquids the suction water should flow from a higher position into the pump, this height being determined by the fact that no evaporation must take place in the suction pipe.

The characteristics of the centrifugal pump are in many respects different, even the reverse, to those of the piston pump. Thus a centrifugal pump can run with the delivery valve shut, producing no dangerous pressure. Generally speaking, at a constant speed with increase in quantity the pressure produced falls, or, in other words, a reduction in the pressure which the pump has to overcome will result in a greater quantity being delivered. Great care should, therefore, be taken in ascertaining, as accurately as possible, the head for which a pump is to be built, as otherwise the pump will possibly not come up to expectations as regards capacity; or if the head upon which the designer based his calculations is greater than the actual head against which the pump has to work, a larger quantity will be delivered by the pump and the load on the driving motor increased.

No bearings should be permitted inside the pump; they should be carried in brackets outside the casing. Stuffing-boxes should not be used as bearings.

Under specially favourable conditions a centrifugal pump made by a first-class firm should attain efficiencies up to 86 per cent.

Solid Matter Centrifugal Pumps.

See Vol. CCVIII. (Dec. 1920), 'Minutes of the Proceedings of the Institution of Civil Engineers,' pages 275–346, and *Engineering*, Jan. 20, 1922.

The impellers in these pumps have flexible blades.

Packing of Centrifugal Pumps.

About nine-tenths of the trouble with centrifugal pumps is due to improper packing. Square flax is generally used, and this soon wears hard, cuts the shaft, leaks badly, and has to be replaced frequently at considerable expense. Soft-flax packing soaked in oil and graphite gives better results, but it lasts only a short time. A 5 in. double-suction centrifugal pump direct-connected to a 15 horse-power motor running at 1,800 revolutions per minute, supplying a barometric condenser, experienced considerable trouble owing to the packing wearing out, the pump taking air, losing the water, and the vacuum; this pump being packed with rawhide packing, after two months' continuous running was found not to leak. The rawhide packing is very economical, as the old packing does not have to be pulled out, and a new ring can be put in on top of the old and kept in the box till it is completely worn out, also the shaft is kept in a good condition. (*Power.*)

Turbo-Pumps.

Victoria Turbo-Pumps.

(*Boving & Co. Ltd., London.*)

The 'Victoria' turbo-pump is a centrifugal pump designed for high and low pressure duty and suitable for dealing with any quantity of water from 60 gallons per minute upwards. There is no upper limit for the quantity dealt with. For instance, two 'Victoria' pumps have been supplied for the Newport Docks for dealing with as much as 100,000 gallons per minute each.

High-Pressure Victoria Turbo-Pumps.

Fig. 21 shows, in section, the arrangement of runners, guide wheels, casings, bearings, etc.

It may be seen from this figure that from entrance to discharge, the passage of the water through the pump is as direct and short as possible. The water flows from the inlet bend into the first impeller, from which it is discharged at its maximum velocity into the guide channels. These are shaped as diffusers, and thus transform the kinetic energy into potential energy (i.e. static pressure) with minimum loss due to friction and eddies. The water then passes round smooth curves into the amply dimensioned diaphragm chamber behind the guide wheel, through which it flows at a low velocity towards the centre to the next impeller, and so on.

An equal additional static pressure is generated by each stage, and the number of stages is therefore directly proportional to the total lift required.

The form of the vanes and channels of the rotating and guide wheels has been carefully designed, and is the result of long experience on test and in actual daily service.

The impellers and guide wheels are all made of special bronze.

For pumps dealing with acid water a special acid-resisting bronze is used.

The inner surfaces of the impeller and guide-wheel channels are carefully finished throughout either by machine or by hand, so that the water during its whole passage through the pump from the first impeller to the delivery casing never comes in contact with any rough surface. This is a most important point, as experience has proved that wheels treated thus have a much longer life when dealing with gritty or muddy water than those having unfinished channels. In addition it is clear that the consequent decrease in friction materially improves the efficiency.

THE HIGH-PRESSURE VICTORIA TURBO-PUMP.

(Boving & Co. Ltd.)

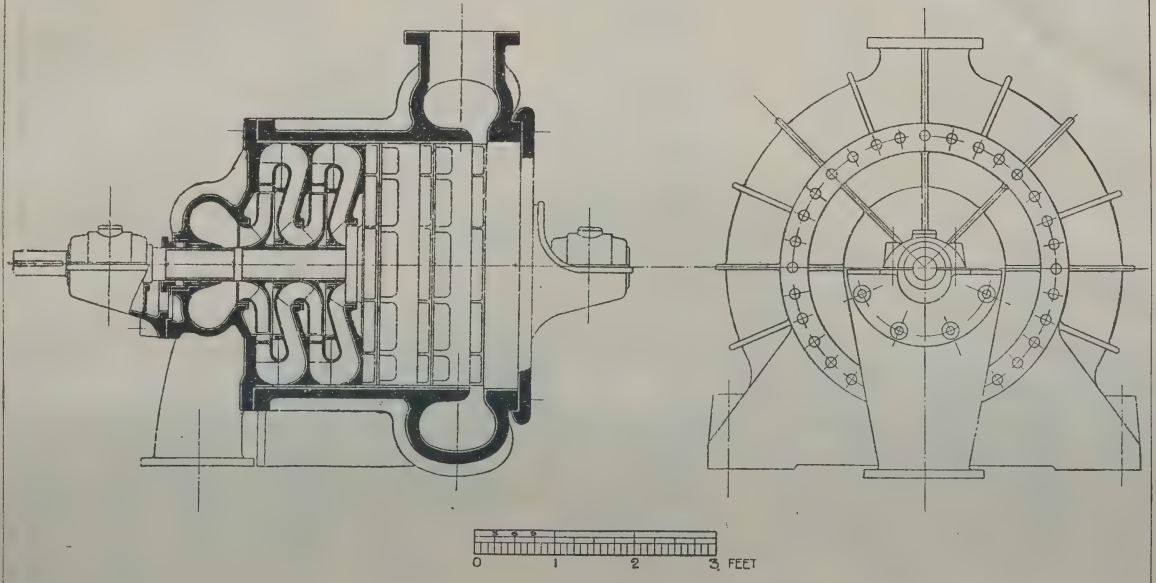

FIG. 21.

The shafts are made of high grade nickel steel to secure strength and rigidity, as well as to resist corrosion. Where the shafts pass through the stuffing boxes they are covered by renewable bronze bushes, and thus protected from wear due to the packing material.

The bearings are cast in one piece with the end covers, which fit cylindrically into the centre casing. It is therefore impossible for any part to get out of alignment if the pump is dismantled. The bearings are of the ring lubrication type, specially designed for high speed. They are separated by a gap of an inch or two from the packing, so that it is impossible for any grit, mud or water to enter. Bearings for sinking pumps have forced lubrication with oil under pressure.

The central casing is of cylindrical bore, and is in all cases lined with special bronze, so that no acid or gritty water comes into contact with the casing at any point. The guide wheels and diaphragms fit cylindrically into the casing. The dismantling and re-assembling of the sundry parts is therefore an extremely easy matter, as they only have to be pushed in one after the other from the open end. It is therefore impossible even for an unskilled erector to get the parts out of true alignment.

Another particular feature of the 'Victoria' pump is that *there is no pressure-stuffing box*, as only low pressure exists in the end chamber behind the last diaphragm. Where pressure-stuffing boxes are used, to avoid undue leakage they have to be screwed up very tight, and the pressure of the packing material on the shaft causes very considerable wear, and also loss of efficiency amounting to as much as 7 per cent.

In the suction end the stuffing box is water sealed, and as it has only to hold tight against $\frac{1}{10}$ of an atmosphere, there is no need to set the packing hard against the shaft.

There is no end-thrust bearing in the 'Victoria' pump as there is no end thrust. This is balanced with absolute accuracy by a special patented arrangement of extreme simplicity which cannot wear or get out of order, and which automatically adjusts itself for changes of head and output while the pump is running, and for any wear that may take place in the impellers.

The 'Victoria' pumps are generally supplied with horizontal shafts, but when required they may be arranged for vertical shafts as well. In this case also the automatic balancing device takes the weight of pump spindle, shaft, and motor armature, and thus provides against any end thrust. The bearings have forced lubrication.

These turbo-pumps are generally coupled directly to electro-motors, but they may also be driven by means of belts or gearing.

Two 'Victoria' pumps have been supplied which are working in a well 150 ft. below the surface, and are driven by vertical shafts of 150 ft. length by means of helical bevel gears from an ordinary line shaft. These pumps work sometimes submerged, sometimes above water level.

For running at other speeds the following rules apply :—

The capacity varies directly as the speed, the head varies directly as the square of the speed.

In the table, page 1160 for each size, two figures are given for the gallons per minute. These represent maximum and minimum figures, and any delivery between these two figures can be arranged for. The two figures for the horse-power correspond to those two deliveries. Also for each size and number of stages two figures are given for the head. Either figure can be arranged for without altering the delivery, by adopting either of two designs of impeller, but not intermediate figures in this case.

Gallons per minute are independent of the number of stages, while the head varies directly as the number of stages.

The speed should always be fixed as high as circumstances permit, as this gives both highest efficiency and lowest first cost.

As an example may be given a pump to deliver 480 gallons per min. against a head of 640 ft., to be coupled directly to an electric motor running at 1,450 revs. From the table this would be a pump with 6 stages and a delivery and suction branch of 150 mm. (6 ins.).

The b.h.p. required would be $480 \div 440 \times 122 = 133$ b.h.p.

In order to reach higher heads than those stated in the table, two pumps may be connected in series, thus dividing the total head into two ; it is desirable that the number coupled together should not exceed two.

Low-pressure Victoria Turbo-Pumps.

These pumps have a very high efficiency, and the design makes them immune to a high degree against the destructive action of grit or mud. Careful tests have proved that more than 80 per cent. efficiency can be obtained for large units, and even for so small a capacity as 2,000 gallons per minute an efficiency of 75 per cent. can safely be guaranteed.

The runners of these low-lift pumps are of the double-wheel type, the water entering these runners symmetrically on both sides, thus ensuring perfect balance from end thrust.

The delivery casing is formed as a spiral in exact accordance with a theoretically-determined curve, so that the water is conducted smoothly off the runner and the great velocity of the water at the outlet of the runner reduced to the velocity in the pipe-line.

The stuffing boxes are water sealed, a bronze lantern ring being inserted between the two packing rings of soft hemp soaked in hot tallow. This ring forms a chamber which is in com-

munication with the outlet of the pump, thus sealing the gland towards the interior of the pump on one hand, and towards the atmosphere on the other hand.

The pump is fitted with ring lubricated bearings separated from the pump casing by an ample gap. Renewable bronze bushes are provided for making a tight joint between the runner and the casing.

The low-lift pumps also may be designed for horizontal or vertical shafts.

Sinking Pumps.

Considerable developments have taken place in recent years in the use of movable pumping units for sinking purposes, and the 'Victoria' pump has been successfully adapted for this purpose. A unit consisting of a vertical pump directly coupled to an electric motor is placed in one frame, the motor being well above the pump; the whole is slung into the pit which it is required to de-water. As the pumping progresses, the pump unit is lowered stage by stage and another length of delivery-pipe is inserted; in this way the water level can be followed.

A large contract for the supply of sinking pumps was awarded by the French Commission (appointed to deal with the reconstruction of the devastated regions in France) to Messrs. Boving & Co. Ltd. This contract included the supply of the necessary sinking pumps for de-watering the various coal mines which were completely flooded during the German invasion. In addition to several units which were rebuilt for dealing with this special work, twelve completely new vertical type motor-driven centrifugal sinking pumps have been supplied, and are now in commission, and at the end of the year 1921 the work of de-watering was proceeding most satisfactorily; it was expected that the complete area would be pumped out during the year 1922. Each of these pumps is run at a speed of 1,460 r.p.m. and is coupled to a vertical type driving motor by suitable flexible couplings, each complete set being mounted in a steel frame, complete with necessary platforms, piping, valves, etc., so that it can be lowered down the pit shaft as the level of the water is reduced. In order to deal with the increasing head of water as the sets are lowered down the pits to keep pace with the lowering of the water level, different sets of impellers are used, these being changed at various set stages, the volume of water dealt with decreasing, of course, as the head increases; the total range varying from a 7,750 gallons per minute, at from 0 ft. to 131 ft. total head, to 1,350 gallons per minute at 800 ft. head. It was estimated that when pumping operations in the flooded coal fields commenced, there were about 100,000,000 cubic metres of water to be raised.

Mather & Platt Centrifugal and Turbine Pumps.

These are of five main types:—

(1) 'Solovane' for low lifts up to 90 ft.
(2) 'Lonovane' for lifts up to 70 ft., and specially designed for Power Station work, condenser circulation.
(3) 'Medivane' without guide vanes, for heads up to 150 ft.
(4) 'Sintovane' Turbine Pump with guide vanes, for heads up to 300 ft.
(5) 'Plurovane' Turbine Pump with guide vanes, for heads up to 3,500 ft.

The 'Solovane' pump, fig. 22, p. 1162, has a single side suction impeller, hydraulically balanced, and delivers water into a carefully designed volute, the entrance to which is obtained by a single vane. It is an efficient yet cheap pump.

The 'Lonovane' pump, fig. 24, p. 1163, has a double suction impeller, and is therefore always in hydraulic balance. There are no guide vanes. The chief feature of this type of pump is its horizontally split casing, also split bearings with split bushes so arranged that the entire pump can be dismantled without disturbing the pipe connections or the motor or machines on either side of the pump, and by simply lifting off the top half of the casing and bearings; this pattern of pump, therefore, is noticeable in regard to accessibility, efficiency, and mechanical design.

The 'Medivane' pump has a double suction impeller, and is therefore always in hydraulic balance. There are no guide vanes, but a carefully designed spiral or volute leads the water to the discharge outlet with maximum conversion of velocity head into pressure head. Impellers of highest quality bronze, removable neck rings and renewable sleeves on shaft where it passes through the stuffing boxes. Bearings are external ring oil-lubricated split bearings and bushes. The general make is high-class, and its efficiency is high. Sizes 6 ins. and over are made with split casings as described for the 'Lonovane' pump.

The 'Sintovane' single-stage pump, fig. 23, p. 1162, is similar to the 'Medivane' in points of impeller and mechanical designs, but is fitted with guide vanes. These vanes are designed to receive the water at very high velocities, and to convert a maximum of this velocity head into pressure head.

The 'Plurovane' pumps, fig. 25, p. 1164, are made with single-entry impellers which discharge water into guide vanes whose function is not only to convert velocity head into pressure head, but also to guide the water into the eye of the next impeller, and so on. Each stage adds the head generated by its impeller to the head delivered to its suction: thus, if one stage generates 100 ft. head, two stages will generate 200 ft., three stages 300 ft., and so on. Each stage is self-contained, having its own body, impeller, and renewable rubbing parts, such as neck rings and bushes. Guide vane tips are also renewable. Impellers and guide vane tips are in special

F, Low or Suction Pressure Chamber.

zincless bronze which is acid-resisting. The sections are held between two end bodies, one of which forms the suction body and the other the discharge body. Bolts passing between suction and discharge bodies hold all the intermediate sections or stages in place. This construction is found by experience to be the most suitable, as the sections can never rust together, and can therefore always be easily dismantled for repairs. The chief feature to be noted in the design is the automatic hydraulic balancing device which does away entirely with thrust bearings and reduces wear to a minimum even on gritty waters. Even when wear takes place the cost of renewals is very slight and can be carried out by removing one small cover. These pumps are principally used for colliery drainage, and have been supplied for heads up to 3,500 ft., the largest pump built requiring about 2,000 h.-p. to drive it.

The turbine pump has been applied to nearly every condition where water, acids, pulp, and most other liquids require to be dealt with, and also for fire purposes.

THE 'PULSOMETER' HIGH-LIFT TURBINE PUMP.

In this pump, fig. 26, the unbalanced axial thrust is taken up inside the pump by a balancing disc fixed on and revolving with the spindle.

The periphery of the disc moves in close contact with a seat fixed to the delivery cover. The space enclosed by the disc and its seat is supplied with water under pressure from the last cell, and this water passes out between the periphery of the disc and the seat into the chamber in which the disc revolves, and then through a connecting pipe back into the suction pipe.

There are no collars on the spindle at the bearings, so that it is free to move axially when the pump is not working, but when working the balancing disc keeps it firmly in position. The system of balancing has the further great advantage that the stuffing box at the delivery end is exposed to suction pressure only, no matter what pressure the pump is working against.

The impellers are not balanced, and the unbalanced area of each impeller causes an axial thrust towards the suction cover.

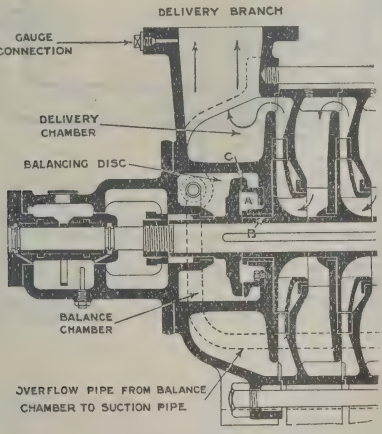

FIG. 26.

The chamber A is supplied with water under pressure from the last impeller, through the clearance B between the spindle and the central bush in the delivery cover.

The axial thrust towards the suction causes the clearance C between the balancing disc and its seat to close up, so that more water enters the chamber A than leaves it, and the pressure in this chamber therefore increases until the axial force on the balancing disc towards the delivery cover balances the axial thrust of the impellers towards the suction cover.

If the axial thrust from the impellers increases, the clearance C closes up, and the pressure in the chamber A increases until equilibrium is again restored.

If the axial thrust from the impellers decreases, the clearance C opens, and the pressure in the chamber A is reduced until equilibrium is again restored.

The balancing disc is made so large that there is no danger of its coming into contact with its seat under the most unfavourable conditions of pumping, such as when the pump is running at full speed with no head.

As there is no metallic contact there is no wear, except when gritty water is pumped, and when from this cause the wear has become excessive, the disc or its seat, or both, can be replaced in a very short time and at small cost, without dismantling the pump, it being only necessary to remove the bearing.

Internal Combustion Pumps.

The Humphrey Internal-Combustion Pump (Gas or Oil).

(William Beardmore & Co., Ltd., 36 Victoria Street, S.W. 1.)

(1)

Fig. 27 represents a diagrammatic view of the Humphrey pump in its simplest form. The arrangement consists of a bent pipe D terminating at one end in a delivery tank E T, and at the other end in a combustion chamber C, in which a charge of gas and air is exploded over the surface of the water. When this explosion takes place the pressure above the water surface sets in motion the whole column of water, the hot gases expanding above it. Once the column of water is set in motion its inertia carries it forward, so that the pressure of the gases in the combustion-chamber ultimately falls below that of the atmosphere,

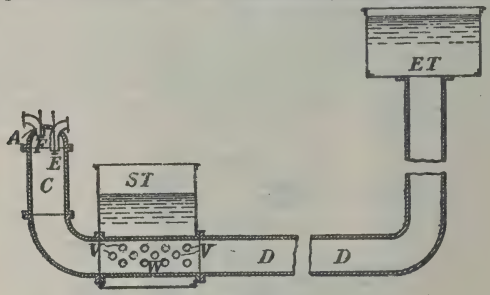

Fig. 27.

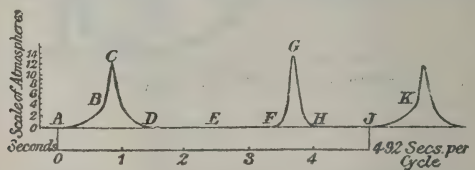
and as a result an exhaust valve E opens under its own weight. The forward motion of the water continuing, the level in C finally falls below that of the water in the supply-tank S T, and fresh water then enters through the valves V. Finally, the momentum being exhausted, the water begins to flow back along the play-pipe D, and rising in the chamber C, closes the valve E by impact, trapping above this level a cushion of the spent gases mixed with a large proportion of air which was drawn in through a scavenger-valve (not shown in the fig.) during the forward motion of the water. This cushion of air is compressed into the head of the chamber by the continued return of the water column, the latter being thus finally brought to rest, in which condition the pressure of the cushion is much above that due to the static head. As a



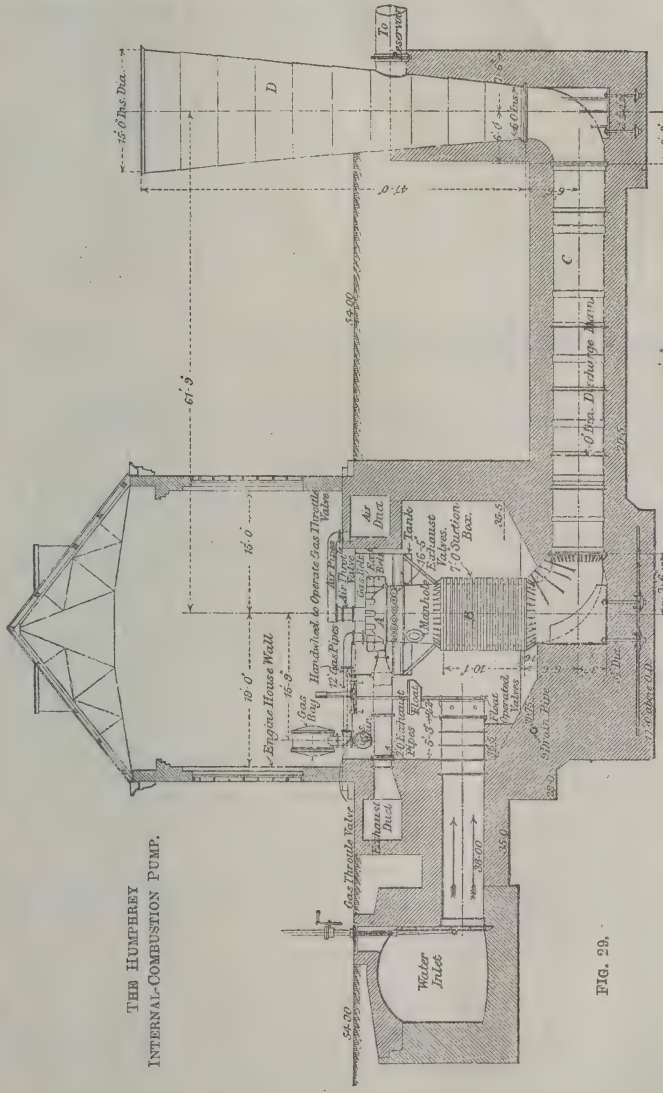


Fig. 28.

consequence the water column begins a second forward oscillation, in the course of which the pressure in the cushion space falls again below that of the atmosphere. By means of interlocking gear the exhaust-valve E and the scavenger-valve are now prevented from opening, but the valve A being simultaneously unlocked, a charge of gas and air enters the chamber. When the forward momentum of the water-column is again exhausted, a return flow takes place, which compresses the new charge and fires it automatically at the proper time, thus starting a fresh cycle of operations.

THE HUMPHREY
INTERNAL-COMBUSTION PUMP.

FIG. 29.

By allowing the water column to swing freely in the manner described, there results a cycle with four strokes of unequal length, such as theory requires.

A comparison of the indicator diagrams, fig. 30 and fig. 31, shows at a glance the extra work obtained by the Humphrey pump cycle (fig. 30) compared with the usual Otto cycle (fig. 31).

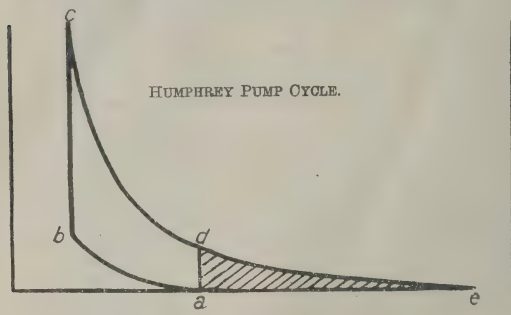

FIG. 30.

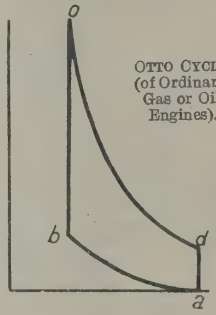

FIG. 31.

Work of Humphrey Pump Cycle . . . = area *abcdea* (Fig. 84).
Work of Otto Cycle (Ordinary Oil or Gas Engines) = „ *abcda* (Fig. 85).
Extra Work obtained by Humphrey Pump Cycle = „ *adea* (Fig. 84).

An indicator (driven by clock-work at a uniform rate), gives a diagram as shown by fig. 27, p. 1166. In this diagram, from A to B, the charge is compressed, being fired at B, which causes the pressure to rise to C; from C to D the gases expand, doing work. The exhaust-valve opens at D, and from D to E there is suction and from E to F slight pressure in the pump chamber. At F the exhaust-valve closes, and compression of the cushion takes place; it will be seen that the maximum pressure attained on this return stroke is in this case higher than the explosion pressure. From G to H the cushion expands, and at H the admission-valve opens, closing again at J on the return of the water-column, to compress the new charge, J being the point at which a fresh cycle of operations is started.

The general arrangement of one of the Humphrey pumps as installed at Chingford (Metropolitan Water Board) is shown by fig. 29, p. 1167). Each pump (which delivers 40,000,000 gals. per diem) has a pump cylinder 7 feet in diameter, and has a cast-steel head A, into which the explosion charge is compressed and fired, a water suction-valve box B, from which a play-pipe C leads to the base of a water tower D, built up of riveted plates. From this tower a 4-foot pipe leads over the top of the reservoir embankment, and discharges into the uppermost of a series of water cushions extending to the bottom of the reservoir. The supply of water is led along the back of the pump-house through a concrete conduit, and from the latter by a cast-iron pipe to the pump pit. The air-duct for the supply is arranged below the floor level on the right of the building, and the exhaust-duct by which the spent gases are passed into the atmosphere, on the left.

Owing to the gases being exhausted at atmospheric pressure, the pump works practically without noise.

The fuel consumption of the pumps (between 250 and 300 h.p. each) was shown by the official trials at Chingford to be 0·904 lb. of anthracite per actual pump-horse-power per hour.

The Humphrey pump is also built to work on a two-stroke cycle; one out-stroke, during which the water is drawn into the pump and delivered, and one in-stroke for compressing the fresh combustible charge. The expulsion of products and replacement by fresh mixture occurs during the period between expansion to atmospheric pressure on the out-stroke and the closing of the exhaust valves on the in-stroke.

The pressure-time diagram will then appear as fig. 28, p. 1166, but with the part from F to J omitted.

The Humphrey pump is particularly suitable for lifts up to 150 ft.

The water is not in the least contaminated by the products of combustion.

Another important application of the Humphrey pump principle, claimed by the makers to give still more economical results as compared with piston machines, is in the compression and exhaustion of air and other gases. Nearly isothermal compression can be obtained, and as there need be no water valves, the apparatus becomes even more simple than a pump.

Pumps, blowers, air compressors or exhausters can be made in very large sizes.

The following claims are made for the Humphrey pump:

1. Absolutely complete expansion of the burnt products, resulting in a great saving of fuel. See figs. 30 and 31, p. 1168.

2. A simple column of water does the same work as, and replaces, 'piston, connecting-rod, crank-shaft, bearings, flywheel, belt, pulleys, and centrifugal or other pump' in other systems, thus eliminating the wear and frictional losses of those parts.

3. The force of the explosion acts directly upon the liquid to be pumped without there being any intermediaries.

4. Practically no lubricating oil is required.

5. There can be no seizing of piston or bearings, and no cooling water is required.

6. The risk of serious breakdown is entirely eliminated.

7. The running and maintenance costs are much reduced.

The Humphrey pump works with large and powerful yet slow strokes, about 15 to 30 cycles per minute, as compared with 200 to 300 r.p.m. of other engines and pumps.

Scoop Wheels.

For raising large bodies of water through a small elevation the scoop wheel is very effective. At Amsterdam the canals are freshened by the drawing of water through them by 8 scoop wheels, discharging to the Zuyder Zee.

Their diameter is 8 m.; breadth, 3·25 m.; capacity, 300 m.^{3} each per minute; speed about 3 revolutions per minute. Floats inclined so that they enter water nearly horizontally, and leave nearly vertically. Height of lift, about 1·5 m.

The tendency to-day is to substitute the centrifugal pump for the scoop wheel even for small elevations.

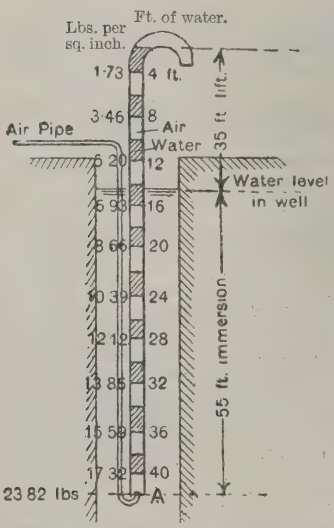
Water Raising from Deep Wells by Compressed Air.

(1)

In this system, air under the necessary pressure, and of suitable volume, is admitted to the foot of a pipe immersed in the water to be lifted, as shown by fig. 32, p. 1170. By this means, alternate bands or plugs of air and water are formed in the water pipe or 'rising main,' and the air does not, as might perhaps have been anticipated, pass through the mass of water. The result of this is that the aggregate weight of the water in the rising main is insufficient to balance the column of water in the boring, and the pressure of the latter therefore produces an upward movement of the air and water column in the rising main. As the force lifting this column is the head of water at A, it follows that the height to which the water can be lifted depends upon the depth to which the pipe is immersed below the pumping level of the water in the boring: thus the higher the 'lift' required, the deeper must be the point at which the air is injected relatively to the normal water level therein, and consequently the height to which the water has to be raised determines the minimum depth to which the boring must be driven.

The following table shows the approximate horse-power required to compress 1 cubic foot of free air to different pressures per square inch:—

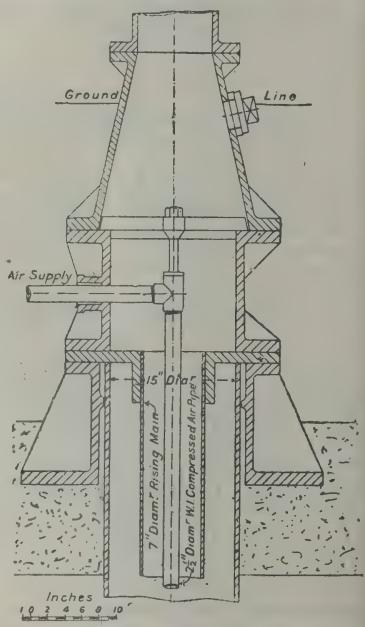
Locality.	Pressure in Pounds per Sq. Inch.	H.p. required to compress 1 Cub. Ft. of Air.	Locality.	Pressure in Pounds per Sq. Inch.	H.p. required to compress 1 Cub. Ft. of Air.
1. Solvay Works, Saaralben	176	0·434	5. Tunbridge Wells Waterworks	60	0·159
2. Brostowe Estate, near Friedheim	140	0·376	6. Sugar Factory, Glogan	45	0·145
3. Tunbridge Wells Waterworks	100	0·201	7. Yard Works, Zwickau	30	0·121
4. Ditto	80	0·189	8. Rossland Mines, B.C.	95	0·134



With regard to the quantity of air required to lift a given volume of water to any specified height, the following formula has been found to give correct results:—

x = cubic feet of free air per minute; A = gallons of water required per minute; B = 'lift of water in feet;

$$x = \frac{A \times B}{125}.$$



The velocity of the air should not exceed about 20 ft. per second.

In considering the design of the compressor, it is obviously important in the interests of economy to provide either 2-stage or 3-stage machines (with intercoolers) according to the amount of compression required; thus for pressures above 60 lbs. per square inch and up to 300 lbs. per square inch 2-stage machines are most suitable, and from this to 1,000 lbs. per square inch 3-stage machines are desirable. The cooling of the air is also of great importance in this respect, and care should be taken to start with an air supply at the lowest temperature obtainable.

Aggregate head of water in rising main, 40 ft. = 17·32 lbs. per square inch.
Aggregate head in well = 55 ft. = 23·82 lbs. per square inch.

FIG. 32.

Detail at top of Bore hole, showing Connection of Air Supply.

FIG. 33.

At Tunbridge Wells the compression is carried out in two stages, the first to a pressure of 25 lbs. per square inch, and the second, after intercooling, to the pressure required, which varies from 90 lbs. to 100 lbs. per square inch according to the depth of the water in the boring. The air is delivered into a large steel receiver situated in the engine-house, whence it is conveyed to the wells by means of a 4-inch cast-iron pipe. This main is formed of ordinary spigot and socket pipes with lead joints, which, however, shortly after starting the plant, showed signs of leakage adjacent to the receiver. This was traced to the expansion and contraction of the pipes due to the high temperature of the air, and was effectually prevented by fixing a cooler on the air pipe between the second stage compressor and the receiver.

There are two sets of engines and compressors, designed to deliver a sufficient volume of air to

lift the desired quantity of water, if need be, over a standpipe 20 ft. high above ground level The engines are compound, with cylinders 8 ins. and 12 ins. diameter respectively, the air-compressing cylinders being 10 ins. (first stage) and 6 ins. (second stage) diameter respectively. The stroke in each case is 14 ins. The air cylinders are water-jacketed at sides and covers. The clearance in the air cylinders does not exceed 1 per cent. of the capacity. The air is drawn from outside the building, and is carried in an earthenware pipe under the floor to the inlet valves, so that it enters the compressors at the lowest possible temperature.

An intercooler (between first and second stages of compressors), formed of a series of 'Row' tubes cooled by circulating water, is fixed outside the engine-house.

The boring is 350 ft. deep. The upper portion is lined with 15-inch steel tubes, and the lower portion (150 ft.) with steel perforated tubes, 13½ ins. diameter. The rest level of the water is about 96 ft. from the surface, and the pumping level, when drawing at the rate of 32,000 gallons per hour, is about 120 ft. from the surface, but on the cessation of pumping the water resumes its rest level very rapidly.

The water pipe or rising main is 7 ins. diameter, and is carried to within a few feet of the bottom of the boring. The air pipe was originally 1½ ins. diameter, but was subsequently increased to 2½ ins. diameter, an alteration which reduced the air pressure required from 105 lbs. to 91 lbs. per square inch, the latter figure corresponding very closely to the head of water above the bottom of the air-pipe, and thus proving the loss by friction to be reduced to a minimum.

In a trial run of 10½ hours made soon after the plant was installed, an average of 31,402 gallons per hour was raised from this boring under a head of 133 ft., whereas an ordinary single-acting pump, such as could be fixed in a boring of this small diameter, would no give more than about 18,300 gallons per hour.

The most favourable result was obtained when the proportion of immersion of air pipe to lift of water was 3 to 1 at the start and 2·2 to 1 at the finish, the volume of air used per volume of water lifted being in the proportion of 2·69 to 1. The efficiency in this case was 36·8 per cent., calculated on the water raised proportionate to the indicated horse-power developed in steam-cylinders, and 46 per cent. calculated from the indicated horse-power shown by air-cylinder diagrams. No record of fuel consumption was made. If the proportion of immersion to lift is reduced the efficiency falls.

From a trial made with a much less immersion of air pipe than in the foregoing, and when the proportion of air used to water lifted was more than double that in the former case, the cost of fuel worked out at 1·073*d.* per 1,000 gallons for a maximum lift of 125 ft. 9 ins., the price of coal being 25*s.* 5*d.* per ton. (*W. H. Maxwell.*)

(2)

In order to enable the well to work successfully and economically, the pipe should be properly proportioned. When the pipe is too large, the water is apt to blow out in a spray and with great force, which is obviously very wasteful both of air and water. When the pipe is too small, the air is apt to rise to the surface of the water in small bubbles, and without producing the desired results. When the air pipe is outside of the water pipe, the proper relation between the diameters of the air and water pipes is as 1½ to 4, which gives a ratio of actual cross-sectional area of 6·24. When the air pipe is situated inside the water pipe, the same ratio of actual cross-sectional areas should obtain, and in this case the diameter of the water pipe is

$$D = \sqrt{\frac{a \times 6{\cdot}24 + A}{{\cdot}7854}},$$

in which a and A represent the actual internal and external areas of the air pipe. The proper areas of the air and water pipes, together with the required depth of submersion and the introduction of the air into the water pipe at the proper point, are the principal factors which determine the success of the air lift.

The water pipe should be submerged to a depth of 18 ins. for each foot lift above the lowest water level in the well; in other words, the best results are obtained when submersion $r = 1{\cdot}5$ the lift, the latter being measured from the lowest, or the working water level, as it is called.

When the well is being worked, the water level falls below the level reached, before water is pumped out. To illustrate the foregoing rule, suppose we wish to elevate water 25 ft. above the surface of the ground, and that when drilling, the well water is obtained at a depth of 40 ft. below the surface. The lift is now 40 ft. + 25 ft. = 65 ft. Applying the foregoing rule for depth of submersion, we have 65 ft. × 1·5 ft. = 97·5 ft., or practically 100 ft., thus giving a total height of 165 ft. from the point where the air enters the water pipe to the point of discharge. After drilling to a depth of 165 ft. − 25 ft. = 140 ft., we are ready to find the working water level in the well. First put the water and air pipes into the well; then drop a float attached to a string into the well. Pass the string over a pulley, and attach a weight to the free end. The weight should be just heavy enough to take up the slack in the string, and at the same time allow the float to descend with the water level as the latter is lowered by pumping. The distance the weight rises will indicate the depth of the working level below the level first obtained in the well, and the latter level should be employed when making calculations involving lift and depth of submersion. A very simple as well as convenient arrangement for measuring the fall of the water level in the well can be made as follows: Take a pulley whose circumference is twelve times the circumference of the shaft upon which the pulley is mounted, then wind the float string around

the pulley, and fasten another string to the shaft, so that it will be wound on the shaft as the float string unwinds from the pulley. It will be seen that this arrangement reduces the travel of the string on the shaft to a convenient length, and one that can easily be measured. Suppose the water level in the well falls 10 ft. The corresponding additional depth of submersion will be 10 ft. × 1·5 ft. = 15 ft., and if the well is not deep enough it should be drilled to a sufficient depth to permit the increased depth of submersion to be obtained, and this is done in order to make the total depth of submersion equal to $1\frac{1}{2}$ times the lift, which proportion, as has been pointed out, is necessary for the best results. If it is not practicable to increase the depth of submersion after finding the working level, the height of the lift may be decreased a corresponding amount; otherwise the efficiency of the lift will be to some extent affected. If the well had been drilled deeper than necessary at the outstart, the increased depth of submersion could readily be obtained by simply lowering the pipes to the required depth. It will be seen that the lower water level in the well also determines the necessary change in the point at which the air should enter the water pipe. With a fall of 10 ft., when pumping, the air should enter the water pipe at from 38 ins. to 40 ins. from the lower end of the pipe; with a fall of 5 ft. the air should enter at from 24 ins. to 26 ins. from the lower end of the water pipe, and with a fall of from 1 ft. to 3 ft. it should enter at a point 18 ins. to 20 ins. from the lower end of the pipe. For other distances the same ratio may be used. A well put down to the depth previously determined and fitted with pipes of the sizes indicated by the rule, can be cemented over, and buildings erected over it, without fear of trouble, because the well will need no further attention, and all that is required is simply to supply it with air as long as the pipes last. A number of wells can, of course, be operated from the same compressor. The necessary machinery can be located in the engine-room, or in any convenient place, and the air pipes run to the different points of distribution.

It is estimated that 1 cub. ft. of air will raise 1 gallon of water, but in wells that are properly proportioned there will be a saving over the amount of from 40 to 47 per cent.: that is to say, the air used will be 60 per cent. of the above estimate as the maximum, and 52 per cent. as the minimum. To illustrate the application of the rule for volume of air required, if we wish to raise 100 gallons of water, we shall need 60 cub. ft. of air as the maximum, and 52 cub. ft. of air as the minimum, the required volume carrying from the maximum to the minimum according to the conditions in each individual case. The average air pressure is 60 lbs. per square inch. When starting to raise water, it requires a somewhat higher pressure, because there is a solid body of water from the surface in the well to the point at which the air enters the water pipe, and this column of water has to be moved by the first discharge of air. When the well has reached its normal working condition, the water pipe will contain a number of short columns of air and short columns of water. These short columns of air and water are discharged alternately, and in the pipe they form a continuous chain, the intermittent discharge continuing as long as the proper amount of air is supplied, and as long as there remains water to be pumped.

TABLE OF SUBMERGENCE AND EFFICIENCY.

Submergence per cent. of Length of Water-pipe.	Efficiency per cent.	Submergence per cent. of Length of Water-pipe.	Efficiency per cent.

(*G. C. H. Fredrich.*)

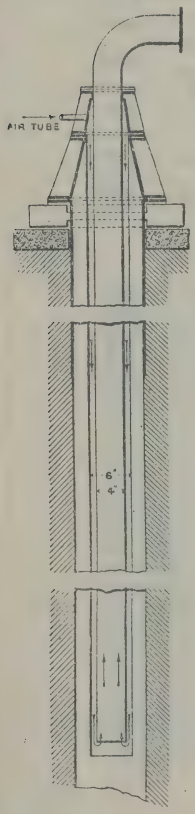

FIG. 34.

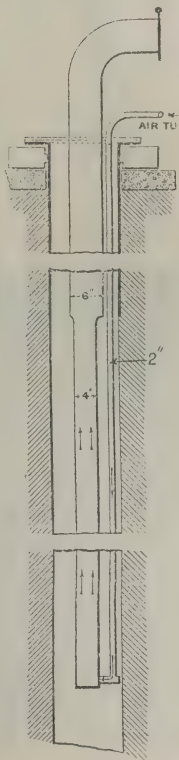

FIG. 35.

At the works of the United Alkali Company, Limited, at Preesall,* a well 450 ft. in depth and 12 ins. in diameter at the bottom is fitted, as shown in figs. 34, 35, with a lining tube going down to the rock-head, and an air tube 6 ins. in diameter, with a delivery tube 4 ins. in diameter inside it, the effective cross-sectional area of the air tube being thus the area of the annulus formed between it and the delivery tube. For working this well a small Ingersoll-Sergeant air compressor was (1906) used.

In another well the delivery and air pipes are arranged on a different plan. In this case the air pipe passes down the well outside the delivery pipe and is connected to it at the bottom, as shown in fig. 35; the air-compressing plant consists (1906) of an Ingersoll-Sergeant cross-compound air compressor, having both the air and the steam cylinders compounded. The speed is regulated by a governor in the usual manner, and also by the pressure of the air as it leaves the high-pressure air cylinder. The air cylinders are water-jacketed, and the air from the low-pressure air cylinder is delivered to an inter-cooler, from which it passes to the high-pressure air cylinder. The air suction valves are carried on the piston, the air passing into the piston through a hollow tail-rod working through a stuffing box and gland on the end of the cylinder, and the delivery valves are controlled by suitable spiral springs. The steam cylinders are 20 ins. and 32 ins. in diameter, and the air cylinders 28·25 ins. and 16·75 ins. in diameter, the stroke being 24 ins. The percentage of clearance in the air cylinders is very small. The air is compressed to 35 lbs. per sq. in. in the low-pressure cylinder, and in the high-pressure cylinder to a pressure ranging between 80 lbs. and

* Kelly ('Proceedings of the Institution of Civil Engineers,' vol. clxiii. May 1906).

120 lbs. per sq. in., according to the depth of submersion of the delivery pipes in the well or wells under operation.

Mr. Rix, in a paper read before the Technical Society of San Francisco, concludes that, with lifts not exceeding 20 ft., 1·5 cub. ft. of air will be required for each cub. ft. of water raised; for lifts of 20 ft. to 50 ft., 2 to 3 cub. ft.; and for lifts of 50 ft. to 100 ft., 3 to 4 cub. ft. will be required. He limits the velocity of the water entering the pipes to 4 to 8 ft. per second.

Air-lift pumping systems are not advisable where the submergence is below 35 per cent., and the best condition for this type of pump is from 45 per cent. to 60 per cent. submergence. By submergence is meant the ratio of the depth of the mixing chamber below the pumping water level to the total height pumped.

With air-lift pumps the hotter the liquid to be pumped the higher will be the efficiency of the pump. It has been shown by Prof. Randall that an efficiency of 100 per cent. is possible under certain conditions when pumping water at 200 deg. Fah.

WATER POWER

EFFICIENCY in Water Turbines is of even greater importance than in most machines, as water power is often very limited and must therefore be utilised to the fullest extent. Good design and workmanship are therefore prime essentials for this class of work and water power users are invited to study the remarkable result we obtained after re-designing and rebuilding five pairs of old type Pelton Wheels for Turbines, each developing 16,000 B.HP., with the remarkable result as shown.

SECTION XXIV

PART III

THE DEVELOPMENT OF WATER-POWER.

(Compiled by Arthur Surveyer, Mem. Canadian Soc. of Civil Engineers.)

WATER-POWER.

The theoretical power or effective energy of a fall of water, in ft.-lbs. per min., is equal to the weight in lbs. of the volume of water flowing per min. over the fall, multiplied by the vertical height of the fall in ft.

$$\text{H.P.} = \frac{Q \times h \times W}{550} = \frac{Q \times h \times 62{\cdot}5}{550} = \frac{Q \times h}{8{\cdot}8}.$$

where,

Q = discharge in cub. ft. per sec.; W = weight of 1 cub. ft. of water = 62·5 lbs.; h = net head or net fall of water in ft.; H.P. = horse-power (33,000 ft.-lbs. per min. or 550 ft.-lbs. per sec.)

For practical purposes, and in order to take into account the losses in the water-wheels, it is better to adopt the following formula, which is based on a water-wheel efficiency of 80 per cent.,

$$\text{Practical H.P.} = \frac{Q \times h}{11}.$$

An efficiency of 80 per cent. is now attained even in the medium-priced wheels, and 90 per cent. is frequently reached in the high-priced wheels. Assuming an efficiency of 88 per cent., then

$$\text{Practical H.P.} = \frac{Q \times h}{10}.$$

Tide-Power.

A horse-power for a day of ten hours would require something like 120 tons of water falling from a height of 100 ft., so that a 500 h.p. factory, say, would need 60,000 tons of water at a 100-foot head. On the basis of 36 cub. ft. of water to the ton, there would thus be over 2,000,000 cub. ft. of water, and this would make a fair-sized pond, say, about 1,000 ft. long, 200 ft. wide, and 10 ft. deep.

The possibilities of tidal power, if it can be developed commercially, are very great.

In Great Britain the highest tides are found in the estuary of the Severn, the mean range of the spring tides at Chepstow being 42 ft., and of the neap tides 21 ft. In France the maximum range occurs at St. Malo, where it amounts to 42·5 ft. at spring tides, and about 18 ft. at neap tides. The tidal range in the Dee is 26 ft. at springs, and 12 ft. at neaps, while the mean range of spring tides around the coast of Great Britain is 16·4 ft., and of neap tides 8·6 ft.

Assuming a mean tidal range of only 20 ft. at springs, and 10 ft. at neaps, and adopting the single-basin method of development with operation on both rising and falling tides, each square mile of basin area would be capable, without storage, of giving an average daily output of approximately 110,000 h.p.-hours. In such an estuary as the Severn, where an area of 20 square miles could readily be utilised with a spring tidal range of 42 ft., the average daily output, without storage, would be approximately 10,000,000 h.p.-hours.

Various storage systems have been suggested. Electrical accumulators must be ruled out, if only on account of the cost, and the same applies to all systems making use of compressed air. The only feasible system appears to consist of a storage reservoir above the level of the tidal basin.

At the present time it is difficult to obtain even a rough estimate of the total cost of such a scheme, owing to the uncertainty regarding many of the factors involved.

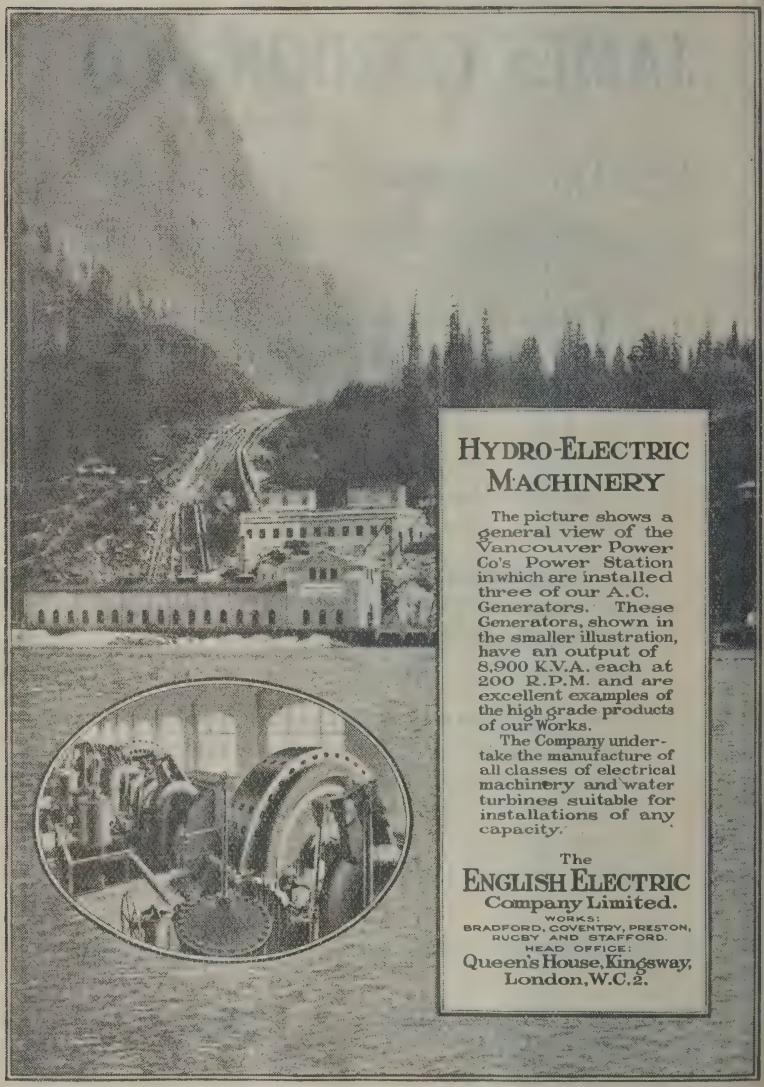
JAMES GORDON & CO.

LTD.

Water Power Engineers

THE Empire contains an abundance of White Coal or Water Power waiting to be exploited.

We have over **20 years experience** in this class of work covering many **hundreds of installations** in all parts of the world under most varying conditions.



This **experience** is at the service of any individual or Corporation that wishes to develop available water supplies for power purposes.

Our **catalogue is a practical booklet** containing such useful information that will enable intending purchasers to form a close judgment of what type of Water Power Plant will be necessary and power available. It will be posted free of charge.

Windsor House, Kingsway, London, W.C.2

HYDRO-ELECTRIC MACHINERY

The picture shows a general view of the Vancouver Power Co's Power Station in which are installed three of our A.C. Generators. These Generators, shown in the smaller illustration, have an output of 8,900 K.V.A. each at 200 R.P.M. and are excellent examples of the high grade products of our Works.

The Company undertake the manufacture of all classes of electrical machinery and water turbines suitable for installations of any capacity.

The
ENGLISH ELECTRIC
Company Limited.
WORKS:
BRADFORD, COVENTRY, PRESTON, RUGBY AND STAFFORD.
HEAD OFFICE:
Queen's House, Kingsway, London, W.C.2.

GENERAL FEATURES OF A WATER-POWER DEVELOPMENT.

Although the lay-out of hydraulic plants changes with every water-power site, there are certain features which are generally found in all developments, and which can be described as follows:

1. The dam, which impounds the water, regulates the level of the upper pool, and directs the water towards the water wheels.

2. The head gates, which control the supply of water, and by means of racks permit the removal from the water supply of injurious floating and suspended matter.

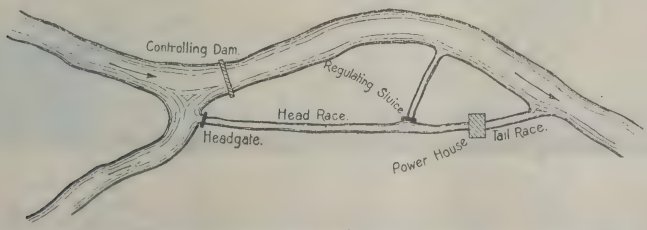

FIG. 1.—Typical General Arrangement of Hydraulic Development.

3. The head race, flume or penstock, which carries the water to the wheels.
4. The power house, which contains the hydraulic machinery.
5. The water wheels, which transform the hydraulic energy.

6. The draft tube, and the tail race, which discharge the water used in the power house into the river.

In some plants the power house forms a part of the dam, and the water is delivered to the wheels without passing through a canal or penstock and discharged back into the river directly through the draft tubes.

Fig. 1 shows a rather complicated lay-out, with a regulating canal for the head race. The regulation of the level of the upper pool is obtained either by a regulating weir, sluices in the dam, or a movable dam.

In approaching the study of any water-power site, the two first things to be determined are the head of water available at all times and the characteristic flow of the river. It is not economical to install machinery which can utilise only the minimum flow of the river, and it is considered good practice to build a plant capable of using the *characteristic flow* of the river, which can be defined as the available dependable flow during at least nine months of a low year.

The available head is determined by levelling and by the daily reading of gauges located in the upper and lower pools of the proposed development.

The *characteristic flow* is found by a series of discharge measurements combined with the daily reading of gauges extending over as long a period as economically possible.

Characteristics of the Flow of Rivers.

The discharge of rivers varies with the precipitation on their drainage basin, the evaporation, the volume of the run off, and the rapidity with which the underground as well as the surface waters reach the river.

The study of drainage basins includes the study of the discharge of streams, of the relations between the stream discharge and the water precipitation, on the drainage basin, on the flood discharges and the rains which cause them, etc.

Discharge of Rivers.

Given a river with an unchangeable bed, there is a fixed relation between the level of this river at a given point and its discharge at that point. Except in the cases of rivers carrying and depositing large quantities of gravel and sand, it is fair to assume that the bed does not change. The discharge curve of a river is obtained from actual measurements, plotted at a suitable scale on cross-section paper. The gauge heights are taken as ordinates and the discharge as abscissæ. The several points thus plotted are connected together by a curve so drawn that the algebraic sum of the squares of the errors is minimum. This curve is a parabola of the form $Q=a+bh+ch^2$. It is often found advisable to develop the discharge equation of a river, and in order to do so the parameters a, b, c can be calculated in each case, from actual measurements, by the method of the least squares.

Measurement of Quantity of Water Flowing in a Stream.

Weir Measurement.

(1)

Rectangular Notch Method.

For small streams a weir dam is used, as shown by fig. 2, consisting of a board long enough to reach across the stream with either end set in the bank. A notch is cut in the board, deep enough

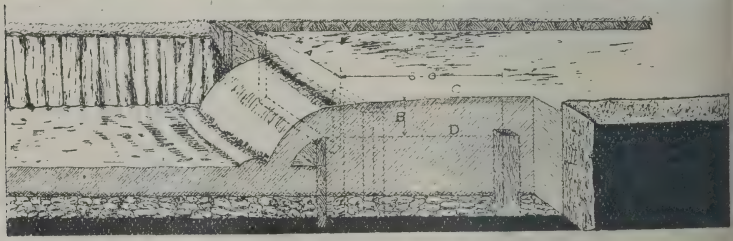

Fig. 2.

to pass all the water, and long enough to reach about two-thirds A, across the stream. The bottom and ends of the notch, D, in the board should be bevelled on the down stream side, leaving the upper edge sharp. The stake, E, should be driven in the bottom of the stream, several feet from the board, on a level with the edge of the notch D. When the water has reached its greatest depth, a measurement, B, can be made of the depth of water over the stake E. The dotted line C represents the top of the running water, and the distance between this line or level of water and the top of the stake gives the true depth or spill over the weir board.

The surface of water below the board should be at least 10 inches lower than the notch D. A part of the stream should be selected where the water can approach the notch quietly.

The weir described above is called a *contracted weir*; if the sides of the notch are continuous with the sides of the channel it is a *suppressed weir*, or a *weir without end contractions*.

According to the different cases we have the following formulæ giving the discharge in cub. ft. per sec.:

With end contractions and a velocity of approach,

$$Q = 5{\cdot}347\ CL\ \sqrt{(H+1{\cdot}4h)^3};$$

where water has no velocity of approach,

$$Q = 5{\cdot}347\ CL\ \sqrt{H^3}$$

without end contractions but with velocity of approach,

$$Q = 5{\cdot}347\ CL\ \sqrt{(H+4/3\ h)^3};$$

where water has no velocity of approach,

$$Q = 5{\cdot}347\ CL\ \sqrt{H^3};$$

in which

L = Length of weir in ft.;
H = Head in ft.;
V = Velocity of approach in ft. per sec.;
h = Head equivalent of velocity of approach = $0{\cdot}01555\ V^2$;
C = Coefficient of discharge;
Q = Discharge in cub. ft. per sec.

The readings obtained at the weir dam are used with the weir table, thus :—

The figures 1, 2, 3, etc., in the first vertical column of the weir table are the inches depth of water running over the notch of weir. The top horizontal line shows fractional parts of an inch ; the body of the table shows the cubic feet and the fractional parts of a cubic foot that will pass each minute, for each inch and fractional inch depth of water in notch. Each of these results is for one inch only of weir, as follows :—

EXAMPLE.—Suppose the notch in board is 20 inches wide and the water at the stake E 5½ inches deep. Take the column containing figure 5 and the one containing figure ½, and the square where they meet contains 5·18 cubic feet. This is the quantity of water passing for each inch in width ; but the weir is 20 inches wide, therefore this result, multiplied by 20, gives 103·6 cubic feet per minute. The same method applies to any depth from one to 25 inches, or any width.

The foregoing only applies in cases where the weir or notch is without end contractions, and discharging from still water.

(2)

'V'-Notch Method.

In this method a 'V'-shaped notch, fig. 3, is cut in the sill board, this notch being of sufficient size to allow the full volume of water to discharge through it. When the flow is steady, then

$$Q = \frac{4}{15}\, kwh\, \sqrt{2gh},\ \text{cubic feet } \textit{per second},$$

w, h, and g being in *feet*.

The value of k varies from ·59 to ·62, according to the angle α, being ·59 for a right angle (90°).

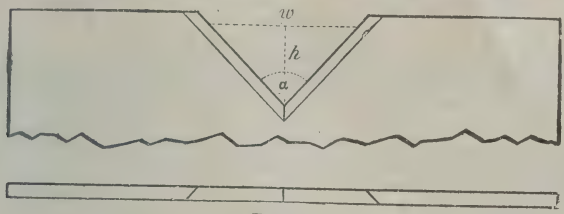

FIG. 3.

When α is a right angle, then $w = 2h$, and formula becomes

$$Q = \cdot 3h^2\sqrt{h},$$ cubic feet *per minute*,

h being in *inches*.

The advantage of the 'V'-notch method is that the ratio of the wetted perimeter of the notch to the area of outflow is the same for any value of h.

A series of 'V'-notches may be cut in the sill-board if the flow of water is great; these notches should be of equal size, and their apexes should be exactly in line, and this line should be exactly horizontal.

When a series of 'V' notches is used, there is a certain amount of mutual interference between the several jets, and in order to get complete immunity from this the notches should be seven times the head apart. If the notches are 3½ times the head apart, the error may be, but would not exceed, ·5 per cent. (*H. S. Rowell. Engineering, May* 2, 1913.)

WEIR TABLE FOR RIGHT-ANGLED 'V'-NOTCH (FROM ONE INCH TO THIRTY INCHES DEEP) GAUGING, GIVING DISCHARGE (Q) IN CUB. FT. PER MIN. FORMULA :—$Q = \cdot 3h^2\sqrt{h}$.

Flow of Water over Sharp-edged Notches and Weirs.

(1) Flow over a triangular notch.

$$Q = 2{\cdot}48nH^{2{\cdot}47}.$$

Q = cub. ft. per sec.; n = tangent of half-included angle of notch; H = head in feet.

(2) Flow over any trapezoidal notch = flow over a rectangular weir of equal length with two end contractions, plus the flow through a triangular notch of corresponding angle.

(3) Flow over a rectangular weir with end contractions varies as—

$$Q = 3{\cdot}10\,L^{1{\cdot}02}\,H^{1{\cdot}47},$$

for all weirs up to at least 19 ft., and for head up to half length of weir, provided depth of post below sill of weir is not less than twice the head. L = length in feet.

General law for trapezoidal weirs:

$$Q = 3{\cdot}10\,L^{1{\cdot}02}\,H^{1{\cdot}47} + 2{\cdot}48nH^{2{\cdot}47}.$$

(*H. J. F. Gourley and B. Santo Crimp, Proceedings Inst.C.E.*, vol. cc. p. 388, Nov. 1915.)

Sluice Measurement.

(*Contributed by J. F. Maryon, M.I.Mech.E.*)

Raise the sluice gate, taking care that the level of the water above the sluice gate is constant, and take the three measurements shown, D being the height from the bottom of the sluice gate to the sill over which the water is flowing, W the width of the opening, and H the distance from

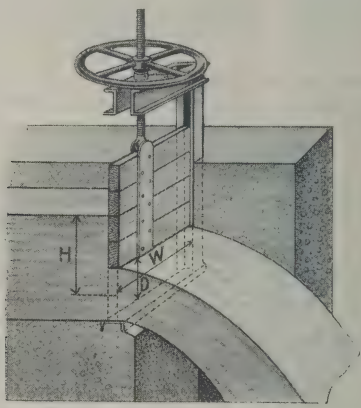

Fig. 4.

the surface of the water above the sluice gate, to a point half-way between the bottom of the sluice gate and the sill. Having obtained these figures in feet, the quantity of water passing in cubic feet per minute is as follows:—

$$Q = W \times D \times 8\sqrt{H} \times 42.$$

Measuring Open Streams.

(*Contributed by J. F. Maryon, M.I.Mech.E.*)

To measure the discharge of a stream it is necessary to obtain by soundings an accurate cross-section of the river at the point of observation. This section is subdivided into a certain number

of sections, A, B, C, D, E (fig. 5), and the mean velocity of flow accurately determined for each sub-section. We have then the relation $Q=A\bar{V}$; where Q=discharge in cub. ft. per sec., A=total area in sq. ins., and $\bar{V}$=mean velocity in ft. per sec., throughout the section.

$$Q=q_1+q_2+q_3+ \ldots . =A_1V_1+A_2V_2+A_3V_3+ \ldots$$

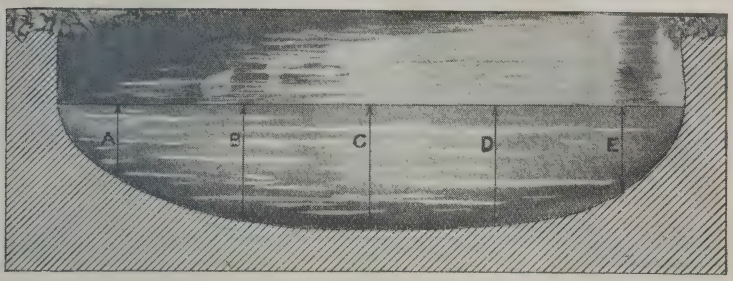

FIG. 5.

The mean velocity occurs at about 0·6 of the depth of a stream, but the mean between the velocities observed at 0·2 and at 0·8 of the depth will also give the mean velocity for the total depth.

MEASUREMENT WITH FLOATS.

In order to measure the velocity of the current in the different sections by means of floats it is necessary to lay out on the shore two parallel ranges perpendicular to the general direction of the current and distant from each other by 200 or 300 ft.

A series of floats are afterwards dropped at a certain distance above the upstream range and their course determined either by transits set up on the shore, or by sextants from a boat kept a few feet distant from each float during its downstream travel.

The passage of each float in line with the upstream and downstream range is recorded with a stopwatch and the mean velocity of the float throughout the distance calculated.

(a) Measurement with Rod Floats.

If a rod float is made to float vertically at a section of the stream so that its lower end is not more than a foot or so above the bed of the river at that point, such a float will be carried downstream by the current at a rate corresponding approximately to the mean velocity of the current at the point considered. It is not always practically possible to fulfil this condition, and even with a complete set of hollow galvanised iron rod floats, which can be sunk at will by loading them with shot, it is found necessary to correct the observed velocity and to reduce it to the mean velocity by using the following formula, due to Francis :

$$V_m = V_r\,(1-0{\cdot}116\,(\sqrt{d}-x)),$$

where V = mean velocity for the vertical section considered ;

V_r = observed velocity of the rod float ;

$d = \dfrac{\text{distance between bottom of rod and river bottom}}{\text{depth of river}}$;

x is a function of $\dfrac{l}{d}$, l being the length of the rod and d the depth of the water.

The following shows the values of x corresponding to various values of $\dfrac{l}{d}$:

$\frac{l}{d}$	0·9	0·8	0·7	0·6	0·5
x	0·10	0·05	0·00	−00·5	−0·10

When $\dfrac{l}{d}=0{\cdot}9$ or more, the formula is that given by Francis:

$$V_m = V_r\,(1-0{\cdot}116\,(\sqrt{D}-0{\cdot}1)).$$

(b) Measurement with Submerged Floats.

It is possible by means of a surface float connected by a string to a submerged float held at a depth equal to about 0·6 of the depth of the stream at that point, to obtain directly without correction the mean velocity in a section. The surface float is generally made very flat so as not to be affected by the wind, and the sub-surface float is generally composed of two pieces of galvanised plate placed cross-wise and terminated at their upper end by hollow tubes in order to give the submerged float the necessary buoyancy.

Measurement by Meters.

The current meters used to measure the velocity of water consist in a wheel of some form so constructed that it is made to revolve by the impact of flowing water, the number of revolutions of this wheel being either recorded, or indicated to the observer. The relation between the velocity of the moving water and the revolutions of the wheel is determined by rating each meter.

Meter Rating.

To rate a meter it is necessary to drive it through still water at a uniform velocity and over a given distance. The distance being known and the time taken to cover it as well as the number of revolutions being noted, it is possible to determine the velocity per second and the number of revolutions per second for this velocity. The experiment must be made at varying speed of translation, so that a complete rating curve can be obtained for each instrument. This curve in all meters is practically a straight line. Meters are not generally reliable for the measurement of velocities of less than 0·3 ft. per sec.

(See also Section XXVI., p. 1311.)

DAMS.

Dams are constructions placed across a stream to impound water, to raise the level of the water upstream, or to divert a part or the whole of the river flow towards the water wheels either by means of a head-race, flumes, or pipes under pressure. Dams can be built with earth, loose stones, timber, masonry, concrete, reinforced concrete, and even with steel. They are fixed or movable according to the needs.

Dams can be built with their crest above the level of the highest waters, and provided with sluiceways, or they can be designed with spillways allowing the water to flow over their crest.

Earth Dams.

Earth dams (fig. 6) can, on account of their large base, be built on less resisting foundations than those constructed of other materials, provided of course that the bed of the river is impermeable. The section of these dams varies according to local circumstances, and with the materials used. In general the upstream slope is either 3 to 1 or 2 to 1, and the downstream slope about 2 to 1. The centre part of earth dams is often constituted by a core of impermeable material, generally a mixture of sand and clay (two-thirds of sand and one-third of clay). Sometimes this core puddle is replaced by a concrete core wall driven into the bed of the river to an impermeable strata. In designing these concrete core walls, it is necessary to make them strong enough to resist the stresses induced by the settlement of the earth embankment.

Rock-Fill Dams.

Rock-fill dams (fig. 7) are also used on uncertain foundations, because the loose stones tumble into place when erosions take place. They are generally given a fair width at the top, with slopes varying between 1 in 1 and 2 in 1; they have the disadvantage of not being water-tight, although they can be made practically so by placing on the upstream slope an impermeable layer of sand and clay. It is not advisable to allow the water to discharge over these dams, and like the earth dams they must be provided with sluiceways and waste gates.

Timber Dams.

Timber dams (fig. 8) are either hollow or filled; the hollow dam consists of a wooden frame covered by an apron on the upstream and on the downstream side and held in place by the weight of water. The filled dams or crib dams consist of boxes made of large pieces of timber bolted together and filled with loose stones. These dams have generally a nearly vertical downstream face and an upstream face sloping 1 to 1 or 2 to 1; they are held in place partly by their own weight and partly by the weight of the water on top of them. They can be used either on solid foundations or on medium foundations: in the latter case, the upstream and downstream toes should be protected by loose stone, in order to prevent erosion.

Masonry and Concrete Dams.

These dams are used principally when the foundation is rock or hard pan, and are generally built with a practically vertical upstream face and a downstream slope of 1 to 1.

Masonry is used chiefly in the construction of storage dams provided with sluiceways, but concrete can be used either for storage dams or spillways.

Reinforced Concrete Dams.
